

GEOCHEMICAL AND FLUID INCLUSION STUDIES OF PEGMATITES FROM  
PARTS OF SOUTHWESTERN NIGERIA

BY  
MATTHEW OYEDELE OYEDOKUN  
B.Sc. (Benin), M.B.A., M.Sc. (Ibadan)  
MATRIC NO:112817

A thesis in the department of Geology  
Submitted to University of Ibadan, in partial fulfilment of the requirements for the  
award of the degree of

DOCTOR OF PHILOSOPHY  
of the

UNIVERSITY OF IBADAN

JUNE, 2019

## ABSTRACT

Geochemical assessment of fluid inclusions in minerals has been successfully used in the description of genesis and characteristics of different ore-forming fluids. However, there are few reported applications of fluid inclusions study in the delineation and characterisation of ore-forming fluids in pegmatites from southwestern Nigeria. This study was designed to determine the type, origin and characteristics of fluids involved in the genesis of pegmatites from parts of southwestern Nigeria.

Systematic geological mapping was carried out in the Olode, Komu and Idiyan areas. Forty-eight samples of pegmatite were subjected to petrographic studies. In addition, 16 whole rock samples of pegmatite and 32 mineral extracts (11 feldspar, 13 muscovite, 8 biotite) were analysed for major, trace and rare-earth elements using inductively coupled plasma optical emission spectrometry technique. Fluid inclusion study was carried out on pegmatitic quartz using microthermometry. Descriptive statistics and geochemical variation plots were used for data evaluation.

Identified lithological units were quartz muscovite schist, sillimanite quartzite, granite gneiss and amphibolite. The pegmatites contained mainly albite, microcline, quartz, biotite and muscovite. Major oxides concentration (%) for pegmatite and mineral extracts were: SiO<sub>2</sub> (35.22 – 82.17%), Al<sub>2</sub>O<sub>3</sub> (0.73 – 34.81%), Fe<sub>2</sub>O<sub>3</sub> (0.1 – 19.79%), MnO (0.004 – 1.693), MgO (0.01 – 8.55%), CaO (0.01 – 2.61), Na<sub>2</sub>O (0.09 – 10.16%) and K<sub>2</sub>O (0.08 – 12.66%), respectively. The concentration (ppm) for Be, Zn, Nb, Sn, Cs, W and Ta ranged as 1.00 – 384.00, 30.00 – 3800.00, 0.60 – 330.00, 1.00 – 319.00, 0.70 – 475.00, 17.20 – 933.00 and 0.32 – 107.00, respectively. Elevated concentrations of Sn were observed in muscovite extracts while elevated concentrations of W were observed in whole pegmatite. Plots of Ta vs K/Cs, K/Rb vs Rb, K/Rb vs Ba, Ta vs K/Cs, Rb vs Ba and Ta vs Cs + Rb showed that the pegmatites were unmineralised to mineralised muscovite class pegmatites. Three types (I, II and III) of aqueous primary to pseudo-secondary inclusions were observed. Type I were two-phase liquid (L)-vapor (V); (L+V; L>V); ~2-100 µm occurring as isolated inclusions, clusters and trails. Type II inclusion was three-phase: Liquid+ Vapor + Solid (L+V+S), ~2 – 15 µm and they occurred as isolated individuals and in trails. Type III were monophasic (liquid) at room temperature and occurred as isolated inclusions, clusters and in trails that also

contained types I and II. Type I inclusion has salinity of 0.7-21.9wt% NaCl<sub>eq</sub>. All inclusions homogenised into the liquid phase at temperature of total homogenisation (Th) of 80.1-335.1°C. Temperature-pressure modelling revealed type II inclusion with Th of 350°C as the earliest fluid trapped and were associated with late magmatic-hydrothermal fluids and type II inclusion were trapped at 250°C. Type I inclusion was trapped at 160-250°C, indicating dilution and interaction of ore-forming fluid with meteoric water while Type III inclusion was trapped at a much lower temperature of <50 °C based on Th values.

The pegmatites of Southwestern Nigeria are characterised by aqueous fluid inclusions of primary and pseudo-secondary types and they are of magmatic to meteoric origins.

## **DEDICATION**

I dedicate this to the glory of God, my darling wife, Funmilayo and children.

## ACKNOWLEDGEMENTS

I give thanks to God for His protection, guidance and wisdom in the course of this research work.

I extend my gratitude to my supervisor, Prof. O. A. Okunlola, for his patience and understanding. I would also like to appreciate all lecturers of the Department of Geology; Prof Elueze (of blessed memory), Prof. A.I. Olayinka (the Vice Chancellor, University of Ibadan), Prof. Adeyemi, Prof. Tijani, Prof. Ehinola (the Head of Department), Dr. Akaegbobi (of blessed memory), Dr Bolarinwa, Dr Nton, Dr Boboye, Dr Olatunji, Dr. Oyediran (research coordinator), Dr Adeigbe, Dr. Osinowo and all non-academic members of staff.

In addition, I would like to thank Prof. T.A. Ewemoje of the Department of Agriculture and Environmental Engineering, Dr. A.A. Ayoade of the Department of Zoology, Dr. M.O. Adeniyi of the Department of Physics for their support and Mrs Bisi Okuntoro Idowu; the secretary to the Vice Chancellor, University of Ibadan.

I will like to express my sincere appreciation to my darling wife, Mrs Funmilayo Oyedokun and children; Ayomide, Ajibola, Favour and Emmanuel, who displayed high level of understanding, during the period of getting the research work done.

The list will be incomplete if I fail to acknowledge the unrelenting support of Mr Emmanuel E. Igonor, Mr Wale Aromolaran, Adekola Taiwo and Adewale Sadiq, Olisa Olusegun; members of staff of the Oyo State Mineral Development Agency; Dr Alessandra Costanzo and Prof. Martin Feely of the National University of Ireland, Galway, and the members of staff of Wagner Petrographic, Utah, United State of America.

I also seize this opportunity to appreciate the support and encouragement of my boss and mentor, the Executive Governor of Oyo State, His Excellency, Sen. Abiola Ajimobi in the course of this research work. I also thank the members of the Executive Council of Oyo State, especially the Deputy Governor, Otunba Moses Alake Adeyemo, the Secretary to the State Government, Alh. Ishmael Olalekan Alli, the Chief of Staff to the Governor, Dr Gbade Ojo, the Commissioner for Environment and Water resources, Chief Isaac Ishola and others.

Also, I thank my big brother, Engr. Rauf Olaniyan for his support towards the achievement of this goal. I thank you all, may the Almighty increase all that you do.

Finally, I will like to appreciate Prof. S.O. Olobaniyi of the department of Geology, University of Lagos and Dr. Olutoyin Fashae of the department of Geography, University of Ibadan.

## CERTIFICATION

I certify that this research work was carried out by **Oyedokun, Matthew Oyedele**, in the Department of Geology, University of Ibadan, Ibadan, Nigeria under my supervision.

# CHAPTER ONE

## INTRODUCTION

### 1.1 General Introduction

With the increase in technological advancement, and the search for new rare metal deposits all over the world, it becomes justified that a thorough study be carried out on the pegmatites of southwestern Nigeria with the intent of unravelling their origin, composition and their economic potential. This will add to the knowledge of the inventory of rare metal mineralisation in Nigeria for economic development.

Pegmatites are coarse grained igneous rocks mostly of granitic origin, composed essentially of quartz, feldspar, mica, which is similar to typical granite. However, they could also be mineralised with garnet, tantalite, niobite, columbite, tourmaline, lepidolite, and other economically viable minerals. For these minerals which pegmatites host, they have become a well sought after and much more explored rock type. These exploration activities have been further boosted by the current drive towards technological advancement and exploration of specialty metals such as tantalite, columbite, tin and a host of other rare metals. Gem mineralisation such as aquamarine, emerald, rubellite, topaz and other valued gemstones are known to be associated with pegmatites.

Pegmatites are generally crystalline, most times intrusive igneous rocks which are composed of interlocking crystals with the crystal size one of the most striking features observable in a hand specimen of a pegmatite which can sometimes grow beyond 5 cm in size.

Pegmatites size varies from veinlets of few centimetres to massive intrusive bodies which could extend for several kilometres. Nature of pegmatite bodies also varies; some occur as dike-like tubular intrusions while some occur as oval, lenticular or pipe-like bodies, lenses, veins, and dikes which are either simple or complex.

Pegmatites are known to serve as hosts to a wide range of economic deposits, such as gemstones, metallic and non-metallic (industrial) minerals. Gemstones;

precious and semi-precious stones such as ruby, opal, emerald, aquamarine, etc., which are used for their aesthetic values in jewellery, ornamental stones, etc. Tantalum (Ta) and Columbium/Niobium (Nb): these are rare metals that invariably occur together. They are used in vacuum tube synthetic rubber, dental and surgical instruments, abrasive, computer and electronics. Lithium (Li) is the lightest of all metals and does occur as native in nature. It is used as alloy of aluminium, magnesium and zinc for light aeroplane metals, ceramic and glass industries etc., while feldspar are used in ceramics industries, and also in the production of fillers in paints, as well as insulating materials in the electrical industry.

Pegmatites, depending on composition, texture and mineralogy, may be simple or complex (zoned). Generally, in unzoned/simple pegmatites which are the most common pegmatite type, mineralogical composition and texture are uniform within the pegmatite with no major variation along the strike. Simple pegmatite show uniformity in grain size from wall with no segregation of minerals; they also possess simple mineralogy of quartz, feldspars and mica; they may contain schorl, garnet as accessory minerals and they are common in metamorphic terranes.

Zoned pegmatites are pegmatites with noticeable textural, mineralogical or compositional dis-uniformity, though zones may not be well developed in certain areas. In zoned pegmatites, different zones which are mappable, non-uniform and differ in texture, grain size and mineralogical composition can be identified; and they are characterised by a core which is surrounded by other outer zones. In zoned pegmatite, grain size increases inwards towards the core of the pegmatite from the outer zones, indicating progressive grain size increase during progressive fractionation of the pegmatite. Furthermore, in zoned pegmatites, from the outer zones through intermediate zones to the pegmatite core, zones may change from an aplitic/granitic texture through graphic/heterogeneous texture in the intermediate zones to large sized coarse grains in the pegmatite core.

Also, in zoned pegmatites, mineralogical variations change from wall to core with the wall having a more complex mineralogy which becomes simpler towards the core, and silica content in the different mineralogical zones increasing towards the zones. In rare metal/rare element enriched pegmatites, different mineralogical zones may contain different elemental concentration of rare metals and rare elements (Okunlola and Ocan, 2009).

Pegmatites commonly occur in groups/swarms, which usually appear to be related to co-genetic large plutons of granitic rock in the area. Based on their distribution with respect to a related pluton, three pegmatite groups: interior, marginal and exterior have been recognised (figures 1.1-1.3) with the least fractionated end of the pluton which has the least complex structural and mineralogical characteristics located within the pluton (interior pegmatites); an intermediate section which lies at the pluton margin (marginal pegmatites), while the third group (exterior pegmatites) lies outside the granitic pluton in the metamorphic country rocks (Černý *et al.*, 1981; Černý, 1991b).

Exterior pegmatites which are complex structurally, texturally and mineralogically, tend to be more common in LCT intrusive—pegmatite system while in NYF pegmatites, interior pegmatites are more common (figure 1.4, Simmons *et al.*, 1987, 1999a, Černý 1991b).

Regional zoning is believed to develop due to the ability of fluid rich in volatiles to travel great distances at lower temperatures and therefore greater distances from the source pluton due to the greater amount of volatiles they contain and their lower viscosity (Černý, 1991a and b). Regional zoning is common in LCT pegmatites and it is influenced by the nature, structure of the host rock, and the vertical level of exposure of the pegmatite. From the related granitic pluton, the mineralogical complexity increases outwards, the degree of fractionation increases while there is a decrease in the number of related associated exterior pegmatites. The sequence is:

- barren to Be-rich
- Be-Nb rich
- Li-Cs-Ta-Sn-rich

With an increase in complexity and degree of evolution of the pegmatite, there is a decrease in the number of pegmatite with one of lepidolite, albite-spodumene or albite, usually present in the most fractionated regional zones (figure 1.2, Černý, 1986). The proposed explanation for this type of zoning is that the more fractionated melts are richer in volatiles. They are therefore less viscous and the volatile-rich fluids remain fluid to lower temperatures and can therefore travel greater distances from the source pluton.

Figure 1.1: Interior to marginal LCT pegmatites (after Cerny 1991b)

Figure 1.2: Regional zoning of LCT pegmatites around a parental pluton (Cerny 1991b)

Figure 1.3: Schematic vertical section through a zoned fertile granite-pegmatite. 1: fertile granites with leucocratic and pegmatitic cupolas, 2: barren to beryl-bearing pegmatites, 3: beryl type, columbite to phosphate-bearing pegmatites; 4: complex spodumene (or petalite) bearing pegmatites (with Sn, Ta and Cs mineralisation), 5: faults, Letters A through D, progressively deeper levels of erosion showing the types of pegmatites exposed (from Cerny, 1986)

Figure 1.4: Relationship between parent granite plutons and surrounding pegmatites showing A) Exterior pegmatites which occurs in a pegmatite aureole surrounds a granitic pluton; B) Marginal pegmatites; C) Interior pegmatites (adapted from Ashworth, 2014)

## 1.2: Formation and classification of pegmatite

There are two different proposed models of pegmatite genesis, fractional crystallisation and anatexis, but fractional crystallisation of a granitic pluton to form pegmatitic melts is the most widely accepted model of pegmatite formation (Cameron *et al.*, 1949; Jahns, 1953; Jahns and Burnharn, 1969; Cerny, 1991b). Based on this model, as the granite crystallizes, the earlier formed minerals are alkali feldspar, sodic plagioclase, quartz and minor muscovite, or biotite and the silicate minerals incorporate Si, Al, K, Na, and minor amounts of Fe and H<sub>2</sub>O from the melt thereby depleting the melt in these constituents and enriching the residual melt in incompatible elements, volatiles and fluxes such as H<sub>2</sub>O, B, F, CO<sub>2</sub>, Li and P. The residual melt therefore has lower viscosity and crystallisation temperature compared to the parent granitic magma, and the melt becomes enriched in rare elements such as Ta, Nb, Cs, Zr, U REE and Sn (Cameron *et al.*, 1949; Simmons, 2007; London, 2008; London and Morgan, 2012).

Two main models exist for crystallisation of pegmatites: fractional crystallisation (Cameron *et al.*, 1949; Jahns, 1953; Jahns and Burnharn, 1969; Cerny 1991b) and constitutional zone refining (Morgan and London 1999). The Jahns, (1953) and Jahns and Burnham's 1969 theory which explained that aqueous fluid interacting with silicate melt is a necessary condition for formation of pegmatite was until recently the most widely accepted theory. However, this has been challenged by experiments of London *et al.*, (1989) who cited a lack of supporting evidence, in particular the low solubility of Al in aqueous fluids. In addition, London, (2008) and London and Morgan, (2012) also cited experimental evidence showing that rapid crystallisation of undercooled melt results in the formation of a boundary layer highly enriched in volatile components.

Fractional crystallisation, however, produces the same effect by the exclusion of incompatible elements as the pegmatite solidifies. The concentration increase is more gradual in fractional crystallisation, but the concentrations of incompatible elements increase exponentially near the final stage of crystallisation (figure 1.2).

London proposed that this process is the mechanism for concentrating fluxes and other incompatible elements into the final products of crystallisation and he refers to this process as constitutional zone refining (CZR). This process allows for the concentration of incompatible elements into the boundary layer without having an initially aqueous vapor-saturated melt. One of the notable differences in the two models is that the Jahns and Burnham model requires aqueous vapor saturation and the London model does not.

The second proposed model for pegmatite genesis is anatexis with the abyssal and muscovite classes of pegmatites proposed to have been formed by anatexis (Cerny and Ercit 2005, Cempirek and Novak, 2006; Grew, 2002), while the rare element class pegmatitic melts are possibly formed by anatexis of rocks with an appropriate composition.

It was also proposed by Simmons *et al.* (1995, 1996) that in an orogenic environment, partial melting of migmatites around plutons could produce melts of similar composition as late-stage melts which are products of fractional crystallisation, thereby implying that pegmatitic melts could be directly produced from low-degree partial melts.

### **Classification of pegmatite**

Different pegmatite classification schemes have been employed over time such as the pegmatite classification studies by Fersman, (1924) and Landes, (1933). But presently, the widely accepted classification scheme is that of Cerny, (1991a) which has been modified over the years to produce other classification other schemes by Cerny and Ercit, (2005) and Cerny *et al.*, (2012).

Cerny's classification scheme of 1991 was based on several factors which includes emplacement depth of the pegmatite, minor elemental composition as well as metamorphic grade and he classified pegmatites into 5 major classes which are:

1. Abyssal (high metamorphic grade, high to low pressure),
2. Muscovite (high pressure, intermediate temperature),
3. Muscovite-Rare Element (high pressure, lower temperature),
4. Rare-Element (low temperature and pressure), and
5. Mirolitic (shallow level).

The pegmatite classes were further subdivided with the exception of the muscovite class into LCT and NYF families based on Li, Cs, Ta, Nb, Y and F elemental concentration while the Rare-Element pegmatite class was subdivided based on mineralogical or geochemical characteristics into different types and subtypes.

Cerny and Ercit, (2005) revised the classification scheme of Cerny, (1991a), they proposed changes on NYF pegmatite classification and produced a petrogenetic classification of pegmatites (table 1.1-1.2).

Martin and De Vito, (2005) also addressed the relationship of pegmatites to tectonic regime. They explained that the LCT and NYF classes cannot be based on

depth-zone classification and they concluded that pegmatites are of two main types, those of anatectic origin and those formed by fractional crystallisation of more primitive felsic plutons. They suggested that the nature/type of parent magma as well as derivatives of rare element enriched magmas are determined by the tectonic setting and they proposed that orogenic suites (compressional tectonic settings) produce LCT pegmatites while extensional tectonic settings (anorogenic suites) produces NYF pegmatites. In addition, they discussed pegmatites with 'mixed' LCT and NYF signatures and 'hybrid' pegmatites which are overprinted by fluids from the wall rocks.

### **1.3: Pegmatites of Nigeria**

Several studies have been carried out on pegmatites in different areas of Nigeria. Raeburn (1927), who was one of the earliest workers of the Precambrian pegmatite of Nigeria, observed that the pegmatites of Calabar were characterised by the presence of tinstone and tourmaline. Jacobson and Webb (1946) in their study of pegmatite in the Central part of Nigeria, concluded that they are of the complex category and that the rare-metals bearing pegmatite of Nigeria are confined to a 400 km long NNE – SSW trending belt stretching from Ago-Iwoye in Southwestern Nigeria to Wamba area in Central Nigeria (figure 1.5-1.7).

Earlier workers such as Jacobson and Webb, (1946) concentrated their work on the geology of pegmatites around plateau tin fields which shows petrographic similarities in the leucogranites of Central and Southwest Nigeria around Wamba and Odoshin near Egbe. They suggested that the formation of the Southwest Nigeria pegmatite is analogous to the pegmatites of Central Nigeria around Wamba. Wright (1970) postulated that widespread pegmatite and aplite development marked the closing stages of the older granite emplacement and further adduced that mineralisation was due to Na rich hydrothermal solutions emanating from the mantle.

Matheis and Caen Vachette (1983); and Matheis (1987) dated the Egbe granites to be 100 Ma older than the 350 Ma recorded for the mineralised pegmatites of the area and postulated that the initial Sr ratios values obtained does not support cogenetic origin for the granites and the pegmatites, and the rare metal rich pegmatites of Southwest Nigeria are products of partial melting of rocks and leaching of the basement units with external fluid supply than truly a pegmatitic phase of proximal older granite.

Kuster, (1990) opined that the evolution of rare metal pegmatites of central Nigeria is related to the late tectonic granite magmatism which is characterised by multiphase intrusion and structurally controlled emplacement. Ekwueme and Matheis, (1995) suggested that the pegmatites appears to have been emplaced along major fault lineaments with albitisation and attendant rare metal mineralisation which may have been due to late stage fluids available at the close of Pan African Orogeny.

**Table 1.1: Pegmatite classification table: Modified from Cerny et al., (2012).**

| Class          | Subclass | Type   | Subtype   | Family |

However, studies by Ekwueme and Schlag, (1989); Ekwueme and Matheis, (1995) and Garba, (2002), show that pegmatites in Nigeria are not restricted to the “Tin Province” or “Pegmatite belt of Nigeria”, but also occur in the southeastern part of Nigeria. These pegmatites are also to extend into northeastern Brazil (Garba, 2002; Ekwueme and Matheis, 1995).

Furthermore, Garba, (2003) delineated some newly discovered rare element pegmatites in Nigeria while Okunlola, (2005) defined 7 broad fields of the Precambrian rare-metals pegmatites of Nigeria namely: Anka-Birnin Gwari, Nasarawa-Keffi, Ijero-Aramoko, Ibadan-Oshogbo, Oke Ogun, Lema-Share and Kabba-Isanlu (figure 1.6-1.7) with rare metal enrichment increasing northwards, from the Ibadan-Oshogbo fields to the most enriched Lema-Ndeji field (Okunlola, 2017).

Okunlola, (2005) in his studies of metallogeny of Nb – Ta mineralisation in Precambrian basement pegmatites of Nigeria noted that rare metal pegmatites are not confined to an older tin belt only. He also noted that low to moderate degree of Nametasomatism (albitisation) control rare metal mineralisation in some Nigerian pegmatites, this shows lower degree of evolution and thus in effect means lower mineralisation compared to other highly mineralised pegmatites in other parts of the world.

Nigerian pegmatites have also been associated with gemstone mineralisation with over ten varieties of gemstones documented mainly around the Ibadan-Osogbo and Oke-Ogun pegmatite fields (Okunlola and Ogedengbe, 2003; Okunlola and Omitogun, 2014) as well as some of the pegmatite fields in the northern central part of the country (Okunlola and Ocan 2009).

Okunlola, (2017) also explained that using geochemical signatures, structural characteristics and petrographic variations, Nigerian pegmatites can be classified into 3 main sub types—Beryl type, Albite type and complex (table 1.3 and 1.4) and some of the pegmatites variably comparable to that of Tanco (Canada), Homestead and Wodgna (Australia) pegmatites, while some overlap with the Buck Noumas rare pegmatite fields of South Africa.

Furthermore, Okunlola, (2017) explained that in some areas, mineralogical zonation are present, though they are complex; they are can be defined and in some pegmatites (for example, Keffi area; Okunlola and Ocan, 2009); they control mineralisation.

**Table 1.3: Classification of granitic pegmatites**

| Class               | Family     | Typical minor element  | Metamorphic environment   | Relation to granite                                      |

## **1.4: Fluid inclusion studies**

### **1.4.1: Background**

Fluid inclusions are minute quantities of fluid with size which are usually 5 – 30  $\mu\text{m}$ , trapped in cavities within minerals (Van der Kerkhof and Hein., 2001). They are vacuoles within minerals which are fluid filled. Fluid inclusion studies in rocks and minerals were developed about 1000 years ago and they were first described in the 11<sup>th</sup> century though they were observed much earlier by ancient Greek and Roman scientists (Roedder, 1984; Leeder et al., 1987).

However, the use of fluid inclusions in the study of geological systems was pioneered by Henry Sorby in the 1800s. Sorby, (1858) reasoned that ‘bubbles’ within fluid inclusions in minerals are a result of differential thermal heating. He explained that systematic increment of the temperature of the inclusions will lead to the disappearance of the bubbles and temperatures at which the bubbles disappear may be used to estimate temperature at which the mineral was formed.

Today, various types of fluid inclusions in minerals have become an invaluable tool in the study of metamorphic and igneous petrology, ore deposits as well as in petroleum geology and if adequately studied, it can provide adequate information on the composition, temperature, pressure and density of ore forming fluid in geological systems:

1. Temperature of mineral crystallisation: fluid inclusions are useful in determination of the trapping temperature of inclusions at different levels of certainty depending on the study method employed and the type of fluid inclusion assemblage (FIA) present. Minimum temperature of trapping of inclusions can be obtained with the temperature of total homogenisation and sometimes, true temperature of trapping of the inclusions may be obtained.
2. Pressure of mineral crystallisation: pressure conditions during mineral crystallisation can also be obtained from fluid inclusion studies. Inclusions can also be useful in determination of true pressure of entrapment in certain cases while in some circumstances, pressure corrections are applied to derive true pressure at the time of crystallisation.

3. Fluid composition: composition of fluids (aqueous or carbonic) can be determined from fluid inclusion studies. Salinity of inclusions can be determined as well as the presence of organics. Other measurements that can be obtained include concentration of organics; identity and concentration of major and minor ion ratios, identity and concentration of dissolved components and gases, identity and composition of available solids as well as isotopic composition of fluids.
4. True temperature and pressure at the time of precipitation can also be obtained from fluid inclusion studies through the use of independent geothermometers such as stable isotope method.

Fluid inclusions occur in all geological environments in different rock forming minerals, but they are best studied using quartz, fluorite, halite, calcite, apatite, dolomite, sphalerite, barite, topaz and cassiterite. In ore deposit studies (porphyry deposits, skarn and hydrothermal deposits), fluid inclusions are best studied in large euhedral crystals in vugs, alterations and veins; in igneous rocks, apatite is used in carbonitite, phenocrysts of volcanic rocks can be studied while quartz is also used.

In pegmatites, minerals which can be used for fluid inclusion studies are quartz, beryl and tourmaline; quartz is from veins and pods can also be used for study in metamorphic rocks, while in sedimentary rocks; diagenetic fluids which are well preserved in pods, vugs, veins and diagenetic cement can be used for fluid inclusion studies.

#### **1.4.2: Classification of fluid inclusions**

Classification of fluid inclusion may be based on the timing of entrapment of the inclusions and also by the type and number of phases present in the inclusion at room temperature. Based on petrographic criteria (timing of entrapment in relation to mineral paragenesis), fluid inclusions can be classified into primary, secondary and pseudo-secondary inclusions. Primary inclusions are inclusions which were formed during mineral growth within the growth zone and they can be identified by their relationship to the growth zones in minerals. They commonly occur along grain boundaries or parallel to growth zonation they range in size and can be of different

shapes (figure 1.8); hence, primary inclusions are good indicators of the conditions of crystallisation of their host minerals.

Secondary inclusions are inclusions which are developed after crystal growth. After crystallisation of a mineral, minute cracks or deformational planes may form in the crystal trapping fluids present during the healing, thereby providing a record of fluids which are present after crystal growth. Sometimes, inclusions are trapped before crystal growth is completed and these inclusions bear all characteristics of secondary inclusions and are termed pseudosecondary inclusions but they terminate at a growth zone boundary while secondary inclusions may appear to cut across different growth zones of a crystal (figure 1.8).

The second classification scheme is based on the type and number of phases (solid, liquid and vapor) which are observed at room temperature in the inclusion (table 1.4). Inclusions are classified into:

1. Monophase liquid (L) inclusions: these are inclusions with 100% liquid content
2. Liquid-rich, two phase (L+V) inclusions: these are inclusions which contain a liquid phase and a vapor phase with a liquid phase occupying a larger percentage (>50%) while the present but smaller vapour phase occupies <50% of the total inclusion volume.
3. Vapor rich, two phase (V+L) inclusions: these are inclusions in which the vapor phase dominates and occupies between 50-80% of the volume of the inclusion with the liquid phase occupying less than 50% of the inclusion volume.
4. Monophase vapor (V) inclusions: these are inclusions which are entirely filled with vapor phase without a visible liquid phase.
5. Multiphase solid (S+L±V) and multi-solid (S+L±V) inclusions: these inclusions essentially contain at least one solid crystalline phase/daughter minerals which is usually less than 50% of the inclusion volume and in, liquid and vapour phases.
6. Immiscible liquid (L1+L2±V) inclusions: these inclusions contain two immiscible liquids; an aqueous phase and a CO<sub>2</sub> rich phase in addition to a vapour phase.
7. Glass inclusions: these are inclusions which contain over 50% of glass.

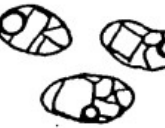

Figure 1.8: Sketch of fluid inclusion classification (Goldstein and Reynolds, 1994)

Table 1.4: Fluid inclusion classification scheme based upon phases observed at room temperature L=liquid, V= vapour, S=solid, GL=glass (adopted from: Shepherd et al., 1985)

| INCLUSION TYPE         | ESSENTIAL PHASES                | TYPICAL EXAMPLES   | ABBREVIATION                        |
|------------------------|---------------------------------|--|-------------------------------------|
| Monophase liquid       | L = 100%                        |    | L                                   |
| Liquid-rich, two-phase | L > 50%                         |    | L + V                               |
| Vapour-rich, two-phase | V = 50 to 80%                   |    | V + L                               |
| Monophase vapour       | V ≈ 100%                        |    | V                                   |
| Multiphase solid       | L = variable<br>S < 50%         |   | S + L ± V                           |
| Multisolid             | S > 50%<br>L, V variable        |  | S + L ± V                           |
| Immiscible liquid      | L <sub>1</sub> , L <sub>2</sub> |  | L <sub>1</sub> + L <sub>2</sub> ± V |
| Glass                  | GL > 50%                        | not shown  | GL ± V ± S                          |

### **1.4.3: Methods of study of fluid inclusions**

Fluid inclusion studies begin with samples selection for production of doubly polished wafers of between 90 and 120  $\mu\text{m}$ . Fluid inclusion petrography involves the determination of the textural relationship of fluid inclusions and the host rock/mineral. It involves observation of different types, generations and populations of inclusions to ensure that fluid inclusions which will be analysed will be representative of the processes which were prevalent during fluid genesis. Different fluid generations can be present in a mineral to be studied due to interaction of minerals with different fluids throughout its geological history. Petrography is therefore used to differentiate between these different set of fluid types and generations; and it provides adequate information on types of fluids present in minerals, the type of fluid inclusion assemblages (FIA) present, abundance of each inclusion type and their relationship/chronology. Fluid inclusion petrography is therefore a very important aspect of fluid inclusion study as it is the key which determines if and how the study should be carried out (Roedder, 1981; 1984; Touret, 2001).

There are various methods involved in the study of fluid inclusions. Fluid inclusion analysis involves destructive and non-destructive methods. Destructive methods of analysis includes mechanical crushing, decrepitemetry, gas and mass spectrometry, crush and leach analysis for bulk analysis; and EPMA/SIMS and LA-ICPMS for single inclusions. Non-destructive analysis methodology includes optical microscopy, microthermometry, Raman spectrometry, laser induced breakdown spectrometry, Fourier Transform Infra-Red etc.

### **1.5: Justification**

Over the years, different researches have been carried out on pegmatites of Nigeria. These studies have been focused on appraisal of the pegmatites for their economic potential and suitability of their constituents for industrial applications with little or no focus on pegmatite genesis. Hence, the study is aimed at determining the fluid characteristics of pegmatites in selected areas of southwestern Nigeria.

### **1.6: Aim and Objectives of the Study**

#### **1.6.1: Aim**

The study is aimed at unravelling the origin and economic mineralisation potential of pegmatites from selected parts of southwestern Nigeria.

### **1.6.2: Objectives**

- i. Determination of the mineralisation potential of the pegmatites.
- ii. Determination of the fluid characteristics of the pegmatite.
- iii. Determination of the origin of pegmatites in the study area

### **1.7 Scope**

To achieve the objectives of the study, the following scope were covered;

- i. systematic geologic mapping of the study areas, with detailed study of field relationship and lithological associations between the pegmatites and host rocks.
- ii. petrographic studies and geochemical analyses of pegmatites and mineral extracts.
- iii. fluid inclusion study using pegmatitic quartz
- iv. determination of the genesis of the pegmatites

### **1.8: Location and accessibility**

The study areas are assessible from different areas. Gonandoya, Abuja Leather, Owode, Idiyan, Omoba, and Balogun-Ojo within the Oke-Ogun pegmatite field while Gbayo, Coco and Falansa are located with the Ibadan-Oshogbo pegmatite field.

Komu, Okeho and Igbojaye can be accessed through the Ibadan-Iseyin road network. Owode and Idiyan can be accessed through the Eleyele – Eruwa road network from Ibadan. Gbayo, Coco and Falansa are easily accessible through the road network in the ancient city of Ibadan through Olomi - Olode road (figure 1.9 – 1.11).

### **1.9: Climate, topography, relief and drainage**

Climate in the study areas is of the typical tropical climate with high temperatures, high humidity with rains from March to October and with temperatures at the peak towards the end of the harmattan period which runs from January to March. (Online Nigeria, 2003).

Average temperatures range 24°C to 25°C during the rainy season with 800-1500mm of rain in different areas. The study areas are mostly drained by rivers with dendritic drainage pattern and vegetation in the study area is characterised by rain forest.

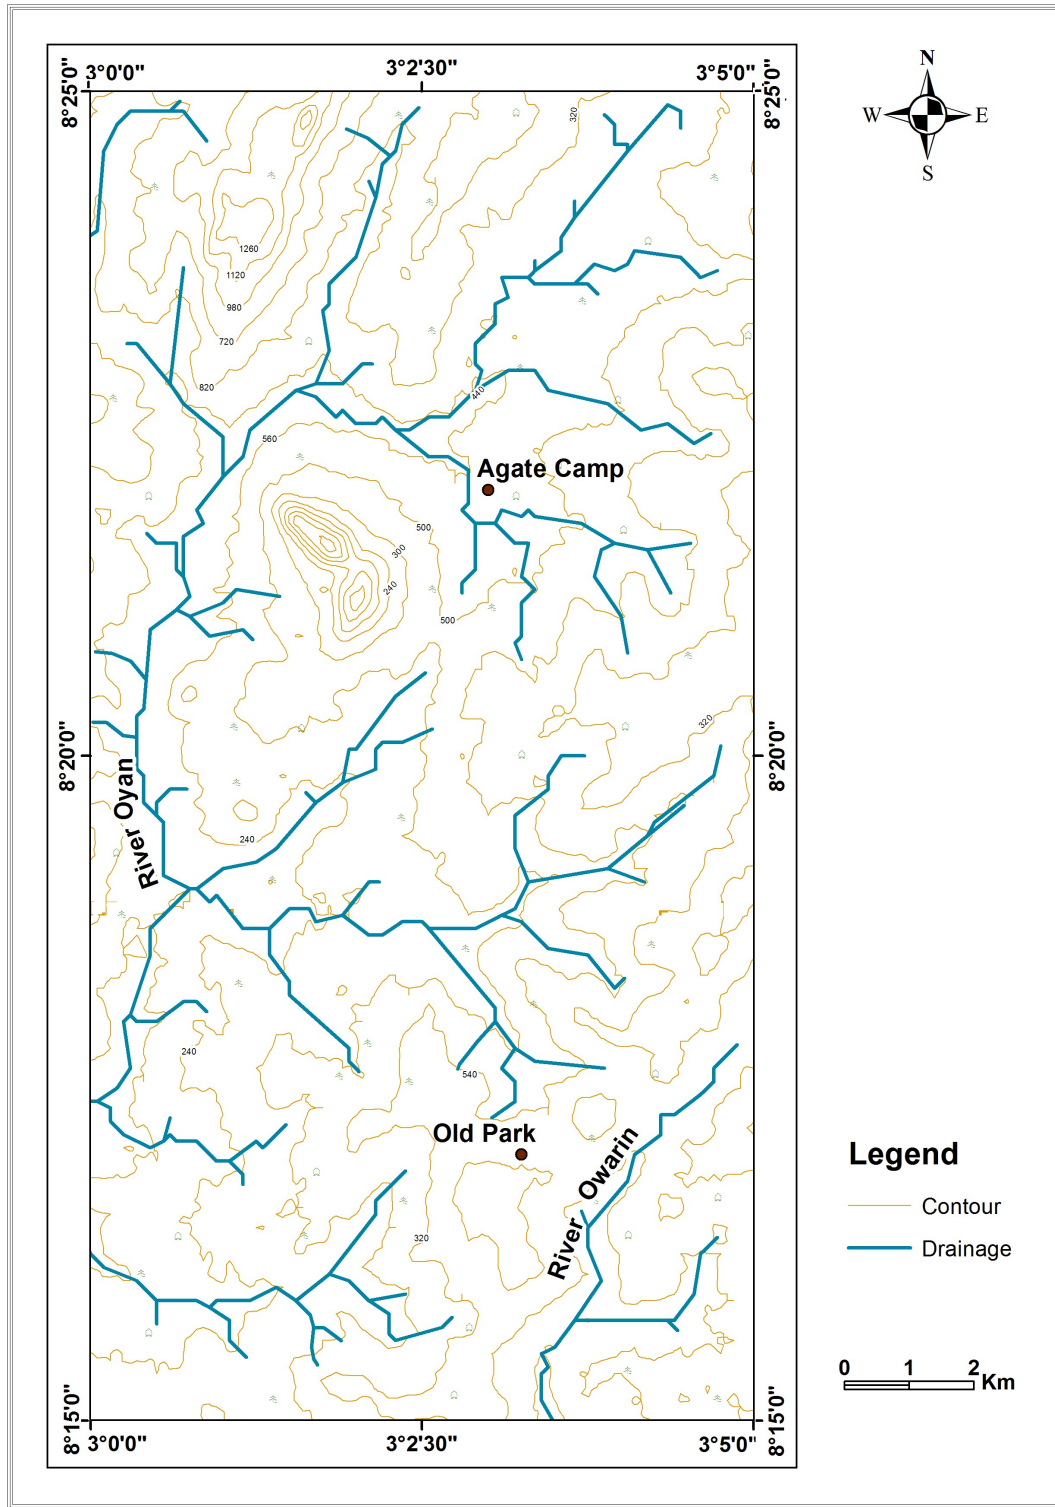

Figure 1.9: Topographical map of Ikomu area.

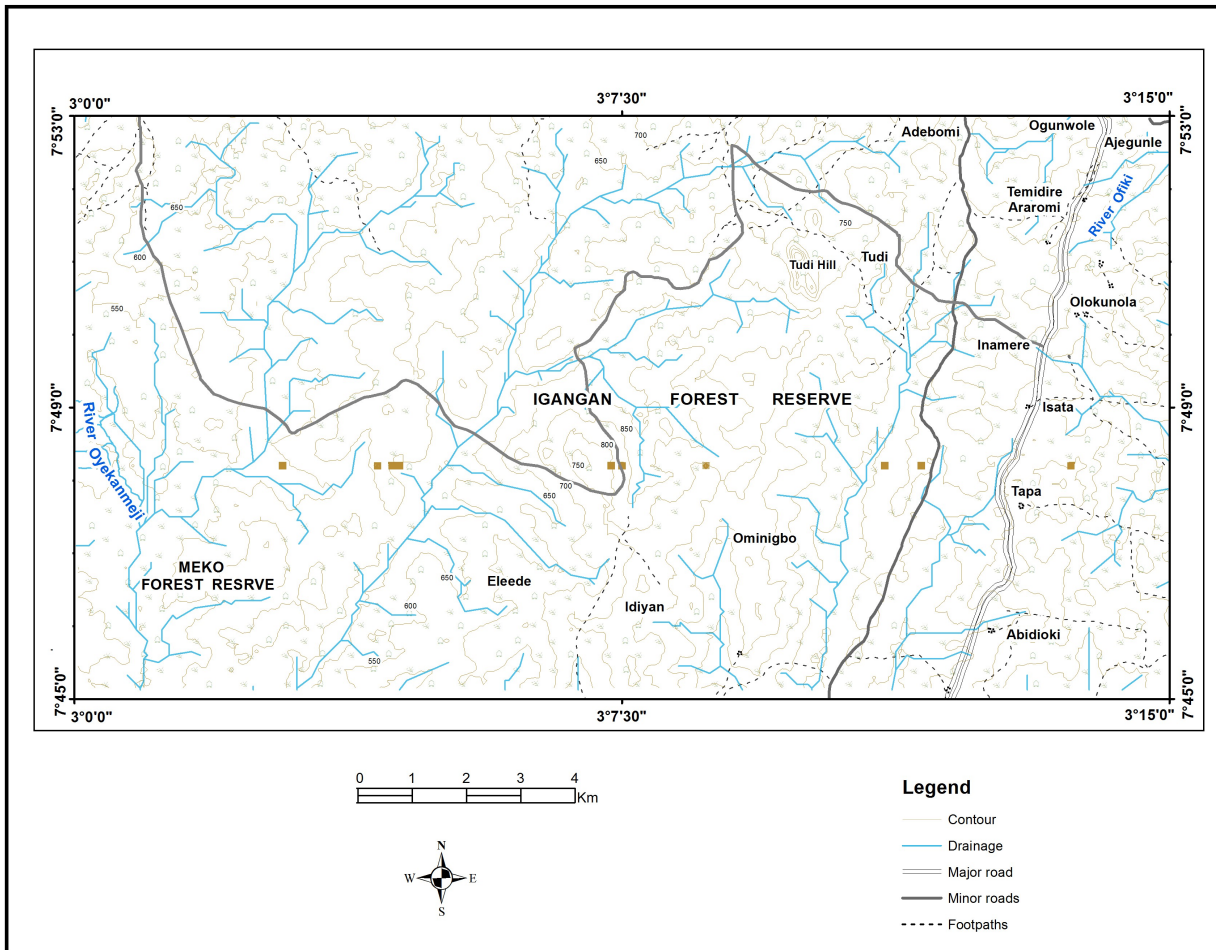

Figure 1.11: Topographical map of Igangan area.

## **CHAPTER TWO**

### **GEOLOGY OF NIGERIA AND REVIEW OF RELATED PREVIOUS WORKS**

#### **2.1: Regional Geology of Nigeria**

Nigeria lies within the boundaries of Latitudes 4°N and 15°N and Longitudes 3°E and 14°E. It is located within the Pan African mobile belt, which is between the West African and Congo Cratons (figure 2.1). Geologically, Nigeria is made up:

- i. The Basement Complex,
- ii. Younger Granites, and
- iii. Sedimentary Basins. (Obaje, 2009).

The basement complex bears imprints of the 600 Ma Pan-African orogeny (figure 2.2). It lies within the reactivated region which was produced by the collision or active Pharusian continental margin and the passive continental margin of the West African craton (Burke and Dewey, 1972; Dada, 2006). These rocks are believed to be results of over four major orogenic cycles (Liberian, eburnean, Kibaran and Pan-African orogeny) between 2700-600 Ma which produced tectonic activities such as metamorphism, deformation and fluid remobilisation.

The Liberian, Eburnean and Kibaran orogenic cycles were characterised by deformation, structural events (isoclinal folding) alongside large-scale regional metamorphism, after which large scale migmatisation occurred. The fourth orogeny involved regional metamorphism, migmatisation, granitisation and gneissification which lead to the evolution of syntectonic granites and homogeneous gneisses (Abaa, 1983). The late stage of the Pan-African Orogeny was typified by the emplacement of different suites of granitic rocks and granodiorites as well as contact metamorphism while fracturing and faulting marked the end of the orogenic episode (Gandu et al., 1986; Olayinka, 1992).

Within the basement complex of Nigeria, there are four distinguishable major petro-lithological units (Figure 8) namely:

1. The Migmatite–Gneiss Complex (MGC),

2. The Schist Belt (Metasedimentary and Metavolcanic rocks),
3. The Older Granites (Pan African granitoids),
4. Undeformed Acid and Basic Dykes.

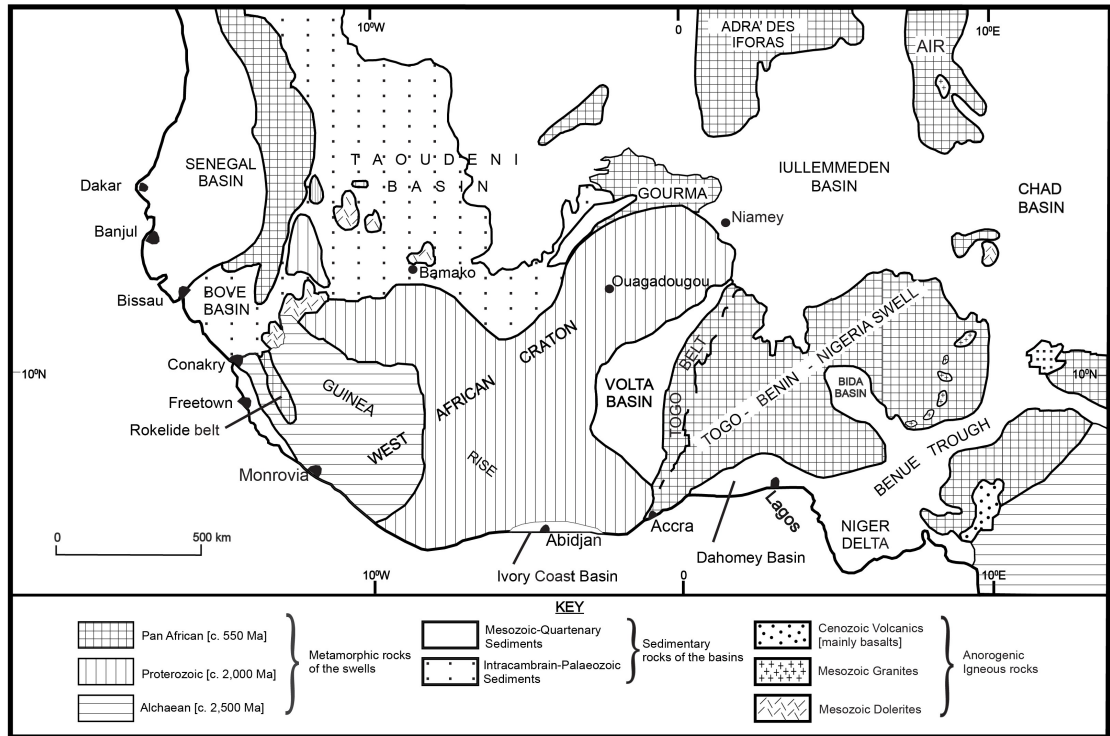

Figure 2.1: Generalised geological map of Nigeria within the framework of the Geology of West Africa (Adapted from Wright, 1985).

### **2.1.1 The Migmatite-Gneiss Complex**

This is the most widespread of the units in the Nigerian basement. The migmatite- gneiss complexes comprised of an heterogeneous assemblage of rocks which include migmatites, ortho-gneisses, para-gneisses, as well as metamorphosed basic and ultrabasic rocks. The mineralogy of these rock units have been reworked by geological processes which are associated with the Pan-African which led to the recrystallisation of a large percentage of the constituent minerals by partial melting. Age of the migmatite gneiss complex ranges from Pan-African to Eburnean with the rocks displaying metamorphic assemblage which ranges from medium to upper amphibolite facies.

This unit makes up a large area of the Nigerian basement (Rahaman and Ocan, 1978) and they record three major geological events (Rahaman and Lancelot, 1984);

- i. the earliest, at 2,500 Ma, which involved crust forming processes and crustal growth by sedimentation and orogeny;
- ii. this was followed by the Eburnean,  $2,000 \pm 200$  Ma, marked by the Ibadan type granite gneisses
- iii. Pan-African event of 900 to 450 which led to structural overprinting of the older rocks and resetting of geochronological clocks in the older basement rocks and also giving rise to granite gneisses, migmatites and other similar lithological units.

### **2.1.2 The Schist Belt (Metasedimentary and Metavolcanic Rocks)**

The Schist Belts comprises of low grade, metasedimentary rocks which are more prominent in the western side of Nigeria (figure 2.2 - 2.3). These N-S trending rocks are as wide as 300km and they have been infolded into the migmatite gneiss rocks complex. Lithologically, the schist belt of Nigeria contains different lithologies which vary from fine to coarse grained clastics, phyllites, pelitic schists, carbonate rocks, banded iron formation and metavolcanics rocks of mafic composition (amphibolite).

Different workers over the years have suggested different origins for the schists belts of Nigeria. Rahaman (1976) and Grant (1978) suggested several depositional basins were involved in the evolution while Oyawoye (1972) and McCurry (1976) suggested they are relicts of a single supracrustal cover. Furthermore, Olade and Elueze (1979) also considered the schist belts to be fault-controlled rift-like structures

while Grant (1978), Holt (1982) and Turner (1983) suggested different ages for the sediments based lithological on structural information while Ajibade et al., (1979) proposed that the schist belt contains series of rocks which have similar deformation history.

Detailed absolute age determination of the schist belts of Nigeria has remained indefinite though the relative ages of the intrusive older granites cross-cuts the schistose rocks and provided a lower age limit of 750 Ma. Rb/Sr dating also provided an age of  $1,040 \pm 25$  Ma as obtained by Ogezi, (1977) and this was accepted as metamorphic age for the Maru Belt phyllites. Finally, the metasedimentary rocks are considered Upper Proterozoic in age.

The schist belts have been mapped and studied over the decades in detail in the following localities: Maru, Anka, Zuru, Kazaure, Kuseriki, Zungeru, Kushaka, Iseyin Oyan, Iwo, and Ilesha where they are known to be generally associated with gold mineralisation.

### **2.1.3 The Older Granites (Pan African Granitoids)**

Falconer, (1911) introduced the term “Older Granite” as a means of distinguishing between the deep-seated granites which are commonly concordant or semi discordant with the Basement Complex and the tin bearing Mesozoic younger granites of North Central Nigeria which occurs as highly discordant granites. It is believed that they are 450-750Ma in age and comprises of believed are pre tectonic, syn-tectonic and post tectonic rocks which cross-cut the older lithologies.

They are representative of a varied and extensive magmatic cycle which is associated with the Pan-African orogeny with varying composition such as tonalities, granodiorites, diorites, syenites and true granites. Rahaman, (1981) noted that they are high level intrusions with anatexis playing an integral role in their evolution. Generally, they generally lack any form of associated mineralisation which might be due to the role thermal effects may have played in remobilisation of mineralizing fluids (Obaje, 2009).

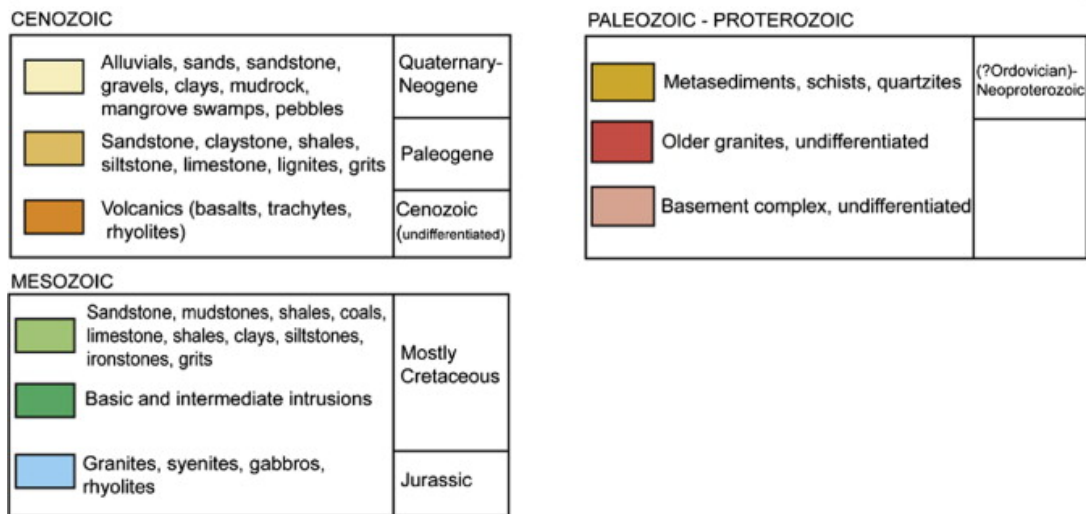

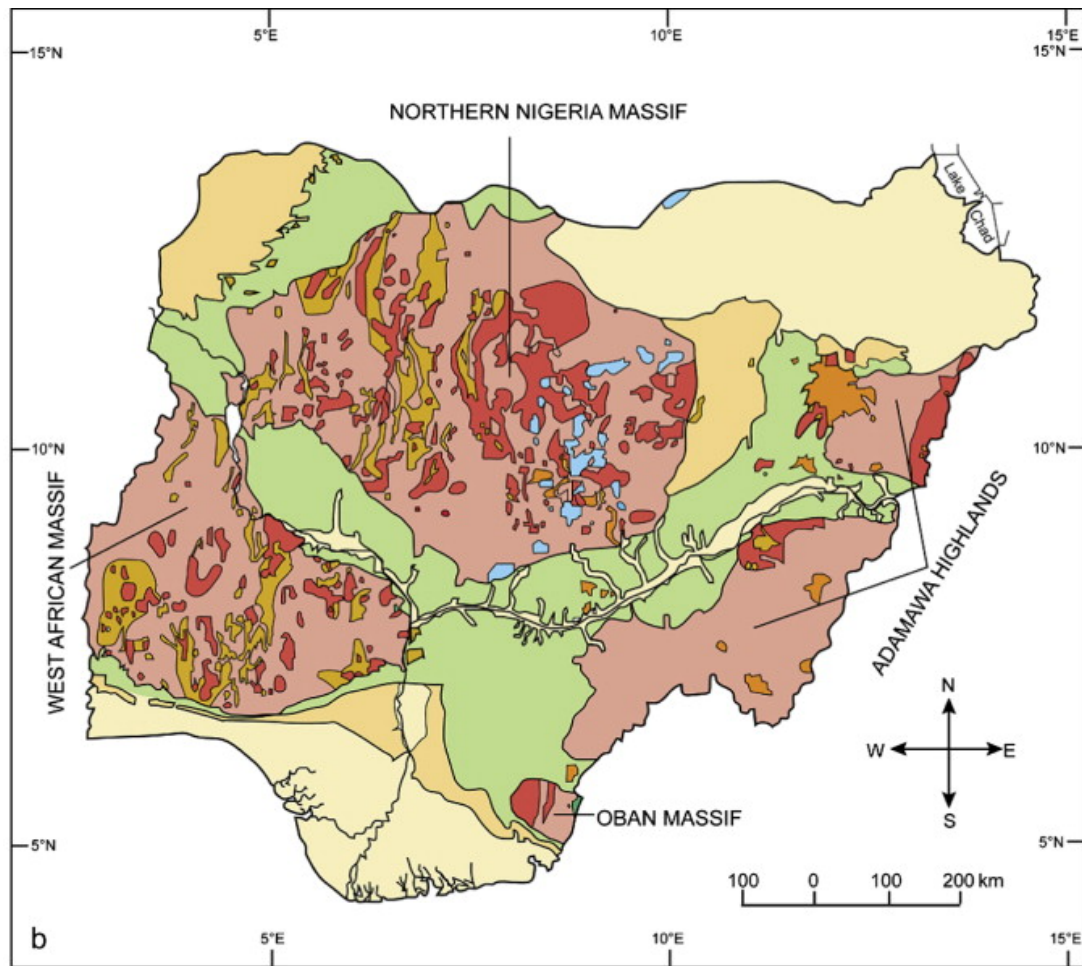

Figure 2.2: Geological Map of Nigeria (NGSA, 2004).

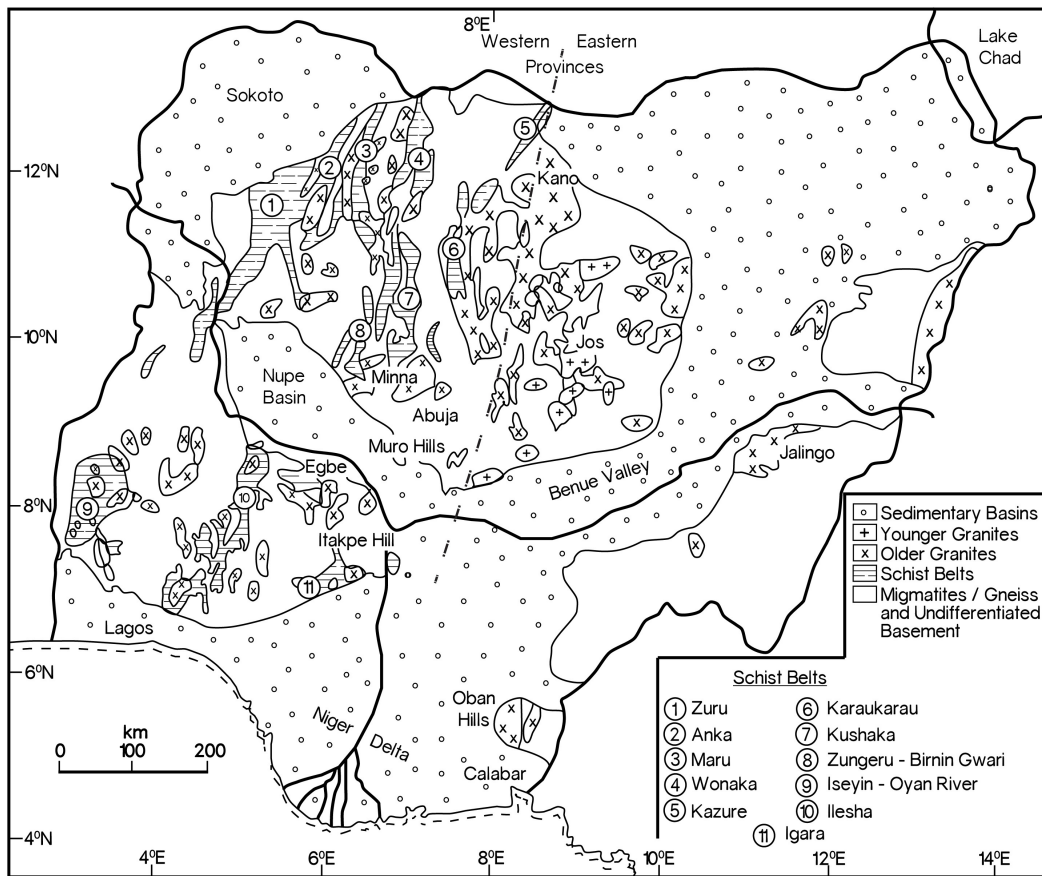

Figure 2.3: Geological map of Nigeria showing the Schist belt (After Woakes et al., 1987).

The older granites also encompass various petrologically important groups which were formed at the same time (Dada, 2006); they occur within the basement complex as the most visible product of the Pan-African orogeny with different levels of addition of materials which may be as high as 70% in some places (Rahaman, 1988). Within the schist belts, various types of granitoids such as biotite granites, charnokites, anorthoites and serpentinites outcrop.

Rahaman, (1988) on the basis of texture, emplacement period and mineralogical variations discarded the earlier classification of members of the Older Granites suite. In its place, based on textural characteristics, he proposed six members of the Older Granite suite as follows:

1. Migmatitic granite;
2. Granite gneiss;
3. Early pegmatites and fine-grained granite;
4. Homogeneous to coarse porphyritic granite;
5. Slightly deformed pegmatite aplites and vein quartz; and
6. Undeformed pegmatites, two-mica granites and vein quartz.

The older granites occur majorly as intrusives associated with the schist belt; and the migmatite gneiss complex rocks. They outcrop at Akwanga, Bauchi, Abuja, Ado-Ekiti, Zaria and Obudu areas.

#### **2.1.4 Undeformed Acid and Basic Dykes**

These are late to post-tectonic rocks which are of Pan African rocks age and cross-cut the Migmatite-Gneiss Complex rocks, the Schistose rocks and the Older Granites. They occur as two groups of intrusive rocks which are:

a. Felsic dykes associated with granitoids of Pan African age on the terrain such as the tourmaline, muscovite and beryl bearing pegmatites, microgranites, aplites and syenite dykes (Dada, 2006),

b. Basic dykes such as dolerites as well as the less common felsite, basaltic and lamprophyric dykes which are regarded as the youngest units in the Nigerian basement.

Geochronological studies have revealed ages of 535-580Ma from Rb-Sr isotopic studies on whole rocks for the felsic dykes (Matheis and Caen-Vachette, 1983; Dada, 2006); an age of 500Ma has been suggested for the basic dykes (Grant, 1970).

## 2.2 Review of related previous works

All over the world, pegmatites have received tremendous attention, which is mostly due to the gemstones, industrial minerals and rare-earth elements they host which play significant roles in technological and economic advancement. However, most of the studies carried out have been focused towards the rare metal and rare earth economic mineralisation potential of pegmatites, with less research on delineating pegmatite genesis using fluid inclusion approach.

Globally, authors who used results from the analyses of mineral extracts to investigate pegmatites. Jiang, (1998) similarly carried out radiogenic isotope studies of tourmaline and opined that stable and radiogenic isotopic studies of tourmaline is a powerful tools for tracing the origin of hydrothermal fluids and for determination of the period of tourmalinisation and associated other hydrothermal alteration, mineralisation or metamorphism.

Quemeneur and Lagache, (1999), did a comparative study of two pegmatite fields in Brazil using results data from the chemical analyses of micas and feldspars. Results indicated that crystallisation mode of the pegmatite fields occurred in a homogenous melt. Scares et al., (2000) studied and tourmaline from pegmatite of Brazil using electron microprobe and Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP-AES) analytical methods and concluded that there are indicative of crystal fractionation as the main magmatic differentiation process for the formation of these pegmatites.

Beurlen et al., (2008) using petrography, scanning electron microscopy-energy dispersive x-ray spectroscopy and U-Pb dating reported that the mineralised pegmatites of the BPP region could have been sourced from associated pegmatitic granite.

Raslan and Ali, (2011) opined that the main mineralizing event in the rare metal pegmatite of Egypt was magmatic with later hydrothermal alteration coupled with local remobilisation of high-field-strength elements. This inference was drawn from the data obtained from heavy mineral analysis, field emission scanning, and X-ray micro analyses of the whole rock pegmatite.

Fredriksson, (2017) studied the rare-element pegmatite bodies of Altim and Tamanduá; in North-eastern Brazil. The two pegmatite bodies were found to have clearly different elemental compositions with high Zn concentration observed in the Altim pegmatite which clearly denotes the two pegmatites as two different formations.

Fluid inclusion study revealed the two pegmatites have different fluid characteristics with low–moderate salinity aqueous-carbonic fluid inclusion in the Tamanduá and moderate–high salinities in the Altim pegmatite. Laser ablation on fluid inclusions revealed Nb and Ta concentrations of 0.1 – 3.2 ppm.

Swanson and Veal, (2010) studied the pegmatites of Spruce Pine District, USA to delineate the mineralogy and petrogenesis. They reported that pegmatites are associated with granodiorites they have similar mineralogy to the granodiorite. The pegmatites varied from zoned to unzoned pegmatite and that the pegmatites crystallized at 20-30km based on feldspar thermobarometry and experimental petrology.

Beurlen et al., (2014) studied the petrogenesis and mineralisation style in the Borborema Pegmatite Province, Brazil. They reported liquidus temperature of 580°C and solidus temperature of 400°C with pressure of 3.8kbar as crystallisation conditions. They surmised that the pegmatite crystallised from a peraluminous melt which was saturated in an aqueous-carbonic fluid of low to medium salinity, peralkaline flux enriched fluid fraction. Based on mineral chemistry studies, the pegmatites are classified as complex-spodumene or lepidolite subtype pegmatite.

Ollila, (1987) also studied the pegmatites of Damaran Orogeny in Namibia. He reported that with respect to Nb, Li, Ta, Be and Sn; the pegmatites are mineralized. Fluid inclusion results from the study revealed that fluid pressure at crystallisation did not exceed 2kb. He surmised that pegmatites crystallised from residual fraction of volatile rich granitic melts during the waning stages of the orogeny.

Deveau et al., (2015) conducted a study on the genesis of LCT pegmatites of French Massif Central using Li isotopes in the mica extracts. They reported  $\delta^7\text{Li}$  values, of -3.6 to +3.4‰ with Li concentration increasing with increasing degree of magmatic evolution of the pegmatite, hence they surmised that partial melting of rare element bearing protoliths is responsible for the isotopic fractionation rather than fractionation crystallisation.

Vapnik and Moroz, (2000) studied the fluid characteristics of inclusions in emerald from Jos, North Central Nigeria using microthermometry and Raman Spectrometry. They reported the occurrence of primary and pseudosecondary inclusions of two types, an highly saline type I inclusion with up to 45% NaCl wt% eq. which contained a low density volatile phase as well as daughter minerals and type II

inclusions which are volatile free and occur with water bearing CO<sub>2</sub> inclusions. They concluded that emerald mineralisation occurred at 400-450°C and 0.2-0.3kbar.

Levasseur, (1997) in his fluid inclusion study of the rare element pegmatite south platte district, Colorado reported concentric zoning with fluorite, Y, Nb and REE enrichment in the pegmatites relative to the associated granite. He reported the presence of four different fluid types in the pegmatites; three sets of aqueous inclusions with salinity of 0-12, 18-24 and 26-30 wt.% eq. and also, a low salinity, CO<sub>2</sub> bearing fluid. He concluded that low salinity fluids were responsible for rare element mineralisation at temperatures of 349-500C, while the other fluid types postdate the mineralisation.

Furthermore, Gagnon *et al.*, (2004) also carried out a study to delineate the origin of hydrothermal fluids in the same NYF pegmatite studied by Levasseur, (1997) with microthermometry and laser ablation ICP-MS. They also reported the presence of four different fluid types in the pegmatites and homogenisation temperatures of 93-149°C. Though the properties of these inclusions could not be detected by microthermometry, LA-ICPMS however revealed detectable differences in Ca concentration in some inclusions while the lower salinity inclusions are characterized by a Na + K+ Sr + Ba solution.

Esmail and Moharem, (2009) carried out a study of fluid characteristics of radioactive mineralized pegmatites in Egypt using microthermometry on pegmatitic quartz and fluorite. They reported that at least two stages of late magmatic hydrothermal alteration was involved; the first stage involved high temperature, low saline fluids while the second stage involved low temperature, highly saline fluids. They surmised that fluid mixing lead to a pH change which remobilised the metals and lead to precipitation of REEs and radioactive minerals.

Whitworth and Rankin, (1989) studied the spodumene bearing pegmatites of southeast Ireland with the aim of evaluating the evolution of the pegmatites from inclusions trapped in quartz. Petrography and microthermometry revealed two different fluid types. Type I inclusions with low to moderate salinities which homogenized at 400°C and type II inclusions which were more saline and homogenized at temperatures below 250°C. Based on pressure temperature modelling, they concluded that type I fluids are associated with magmatic/hydrothermal fluids from the associated granite.

Ackerman et al., (2007) also carried out a thermobarometric and fluid evaluation of pegmatites from the Bohemian Massif, Czech Republic using fluid inclusions on quartz, fluorite, titanite and apatite. Two fluid types were identified; an early aqueous-carbonic fluid and a late aqueous fluid; the barren pegmatites are associated with  $\text{H}_2\text{O}-\text{CO}_2$  low salinity fluids of 2-6 wt % eq while fluids associated with Li mineralized pegmatites are more saline and contain  $\text{H}_2\text{O}-\text{CO}_2/\text{N}_2-\text{H}_3\text{BO}_3-\text{NaCl}$ . They reported P-T conditions of 600-640 °C and 420-580Mpa for barren pegmatites and 500-570 C and 310-430MPa for Li mineralized pegmatite.

Zarasvandi et al., (2014) also carried out a fluid investigation of the Farsesh barite deposit, Iran using microthermometry. They identified two types of primary/pseudo-primary inclusions with low salinity values of 4.2-20 eq wt% NaCl which homogenized into the liquid phase at low homogenisation temperature of 125-200°C and they concluded that the barite deposited precipitated from hydrothermal basinal fluids of low to medium salinity.

Shafaroudi and Karimpour, (2015) examined the evolution of the Sechangi lead-zinc deposit of Eastern Iran using mineralogical, fluid and sulfur isotopic characteristics. Microthermometry results revealed homogenisation temperatures of 151-352°C with salinity of 0.2-16.5 wt. %NaCl eq. They surmised that ore forming fluids are low-medium temperature and low-medium salinity with fluid mixing playing an important role in mineralisation.

Sasmaz and Yavuz, (2007) also carried out a study to investigate the genesis and physiochemical conditions of fluorite mineralisation in syenites of Yildizeli-Sivas, Turkey using geochemical method and microthermometry. They reported that fluorites in the study area have characteristics which are typical of primary crystallisation and remobilization based on REE geochemistry and they were formed from fluids at temperatures of 161-243°C.

Oyebamiji, (2013) studied the compositional characteristics of pegmatite bodies in Oro, southwestern Nigeria with a view to elucidating the rare metal mineralisation characteristics. He surmised that the pegmatites in the areas are mineralized.

Taylor and Friedrichsen, (1983) studied the stable isotopic characteristics of the Landsverk pegmatite, Norway. They reported light  $^{18}\text{O}$  values which are characteristic

of meteoric-hydrothermally altered rocks and  $\delta D$  values in one fluid inclusion which supports evidence of the presence meteoric water in the area.

Garba and Akande, (1992) studied the origin and significance of the carbonic inclusion associated with gold mineralisation in Bin Yauri, northwestern Nigeria. They reported that fluid immiscibility of low salinity  $CO_2$  rich hydrothermal fluids lead to selective entrapment and loss of  $H_2O$  phase during gold mineralisation which lead to increased oxidation effects. The fluids are believed to have originated from dewatering of subducted metasedimentary rocks along the Anka fault system.

Sirbescu and Nabalek, (2003) examined the petrogenesis of the Tin Mountain pegmatite in South Dakota, USA. They reported the presence of Dawsonite in primary inclusions within pegmatitic quartz and this confirmed using SEM-EDS and Raman spectroscopy. They explained that the presence of the mineral is evidence of carbonate ions in pegmatite evolution and carbonates, as well borate minerals play important roles in pegmatite formation.

Arribas *et al.*, (1995) studied the gold alunite deposits of Spain using a combined approach of geology, geochronology, fluid and isotopic characteristics. Based on results from fluid and isotopic studies, an hydrothermal system characterized by an early acidic wall rock alteration and late gold mineralisation was inferred. They also reported that the presence of a significant magmatic fluid and salinity values in inclusions which are higher than 40% wt. eq. NaCl.

Akcay *et al.*, (1995) in their study of the fluid characteristics and chemistry of tourmalines from the Sb-Hg<sup>+</sup> W deposit of Niode massif, Turkey reported that tourmalinasation is a common feature of associated granitic rocks. Fluid characterization of the tourmaline revealed salinity measurements of 5.5-10.5 wt. % eq. NaCl which may be indicative of a magmatic origin for the tourmaline.

## **CHAPTER THREE**

### **METHODOLOGY**

#### **3.1 Field methods, mapping and sampling**

The study involved systematic geological mapping of selected areas within the Ibadan-Oshogbo and Oke-Ogun pegmatite field to delineate the geology and obtain representative samples of pegmatites. Geological mapping involved observation of the pegmatites and the associated lithologies as well as basic pegmatite mineralogy.

#### **3.2 Sample preparation**

From the systematic mapping exercise, 58 samples of pegmatites were collected; samples with very low degree of alteration were selected for thin section and geochemical analysis. Thin sections were prepared at the Department of Geology, University of Ibadan while doubly polished wafer were prepared at Wagner Petrographic, Utah, United States of America.

#### **3.3: Geochemical analysis**

Pegmatite samples from five areas (Komu Olode gbayo Idiyan and Owode) in the Oke-Ogun and Ibadan-Oshogbo pegmatite fields were collected. Unaltered samples of pegmatites were selected and 48 samples comprising of 16 whole rock samples, 11 feldspars extracts, 13 muscovite extracts and 8 biotite extracts were pulverised at the petrological laboratory of the Department of Geology, University of Ibadan and thereafter analysed at Activation Laboratories, Ontario, Canada for major, trace and rare-earth elemental concentrations using Inductively Coupled Plasma Optical Emission Spectrometry (ICP-OES) and Inductively Coupled Plasma Mass Spectrometry (ICP-MS) techniques.

### **3.4: Fluid inclusion study**

#### **3.4.1: Sample preparation and instrumentation**

The doubly polished wafers were studied at the Geofluids Research Laboratory (figure 3.1); National University of Ireland, Galway to develop a fluid inclusion paragenetic classification using transmitted light microscopy with a Nikon Eclipse E200 polarising microscope. Microthermometric analyses were carried out using a Linkam THMGS 600 heating-freezing stage, mounted on an Olympus transmitted plane polarised light microscope (figure 3.2 - 3.3) equipped with a long working distance objective lenses with up to 100x magnification.

Figure 3.1: Pictures of the doubly polished wafers of pegmatite samples

Figure 3.2: Transmitted Plane Polarised Light Microscope fitted with an incident UV light attachment used for microthermometric analysis of fluid inclusions at Geofluids Research Laboratory, National University of Ireland, Galway

Figure 3.3: Transmitted Plane Polarised Light Microscope fitted with a stage mounted Linkam heating and cooling stage used for microthermometric analysis of fluid inclusions at Geofluids Research Laboratory, National University of Ireland, Galway

### **3.4.2: Fluid inclusion petrography and microthermometry**

Fluid inclusion petrography involves the determination of the types and generation of fluid inclusion in the doubly polished wafers as well as their properties. Microthermometry is a non-destructive fluid inclusion study analytical method. It is the most common method and it is used in the determination of physical and compositional properties of the inclusions. It involves cooling and heating of the inclusions in order to determine fluid composition, salinity and density through the observation of subtle phase changes. Inclusions were subjected to cooling up to  $-100^{\circ}\text{C}$  and phase changes were measured during progressive heating. After all low temperature measurements were obtained, heating was carried out up to temperatures of  $450^{\circ}\text{C}$  to determine the homogenisation temperature. Measurements obtained during microthermometry for the study are the temperature of last melting (TLM) and the temperature of homogenisation ( $T_{\text{H}}$ ).

### **3.4.3 Fluid Inclusion Microthermometry**

Aqueous fluid inclusions were subjected to cooling/freezing and heating to observe and record the temperature at which phase changes occur. Temperature of first ice melting (TFM) and temperature of last ice melting (TLM) were recorded by cooling the inclusions to temperatures in excess of  $-110^{\circ}\text{C}$  and the heating..

- The TFM is equivalent to the eutectic melting point of an aqueous saline solution. TFM values below  $-20.8^{\circ}\text{C}$  are indicative of other salt components in the solution (e.g. Ca or Mg).
- TLM values are used to estimate the salinity of the fluid. The TLM values are indicative of the type of salts available in the aqueous solution and TLM is reported as equivalent weight % of NaCl.

Subsequent heating of the two-phase (liquid + vapour) aqueous fluid inclusion, allows for measurement of the temperature of homogenisation ( $T_{\text{H}}$ ). This is the temperature at which liquid and vapour phases homogenise to the single phase and yields a minimum fluid trapping temperature for an aqueous fluid inclusion. Isochores were thereafter constructed using the program FLUIDS of Bakker, (2003).

Two samples were collected from the same pegmatite (i.e. two samples from each of five pegmatites), therefore the microthermometric data is presented as a series of paired samples to reflect this.  $T_{\text{H}}$  and salinity data for each sample pair is presented

as frequency distribution histogram (frequency versus  $T_H$ ) and bivariate plots ( $T_H$  versus salinity).

The microthermometric data includes temperature of last ice melting ( $T_{LM}$ ), temperature of total homogenisation ( $T_H$ ) and salinity (equivalent weight % NaCl).

## **CHAPTER FOUR**

### **RESULTS AND DISCUSSION**

#### **RESULTS**

##### **4.1 Geological setting of the study areas**

Pegmatite samples from different areas were used for the study. The geological settings of the areas are described below:

##### **4.1.1: Geology of Olode-Falansa-Coco area**

The geology of the study area comprises the geology of Ibadan, Oke-Ogun and Ibarapa zones. The geology of Olode-Falansa area comprises of rock types; granite gneiss, sillimanite quartzite, medium grained granite and pegmatite. The granite gneiss was observed to occupy the eastern half of the area. Granite gneiss in the Olode area are characterised by alternating bands of felsic and mafic minerals, they are medium to coarse grained and are closely associated with pegmatites in the area (figure 4.1-4.3).

N-S trending sillimanite quartzites also outcrop in the area with gradational contact with the granite gneisses and granites. The granites in the Olode area are low lying in some areas and are massive outcrops in other areas, they are medium grained.

In the Olode area, pegmatites occur as NE-SW trending outcrops of various shapes, sizes and length. They are composed of quartz, plagioclase, orthoclase and muscovites, while tourmaline, beryl, garnets are associated accessory minerals (figure 4.4- 4.6).

Figure 4.6: Photomicrograph of a section of pegmatite from Coco in transmitted light showing presence of Microcline (Mc), Muscovite (Ms) in abundance and Quartz (Qz).

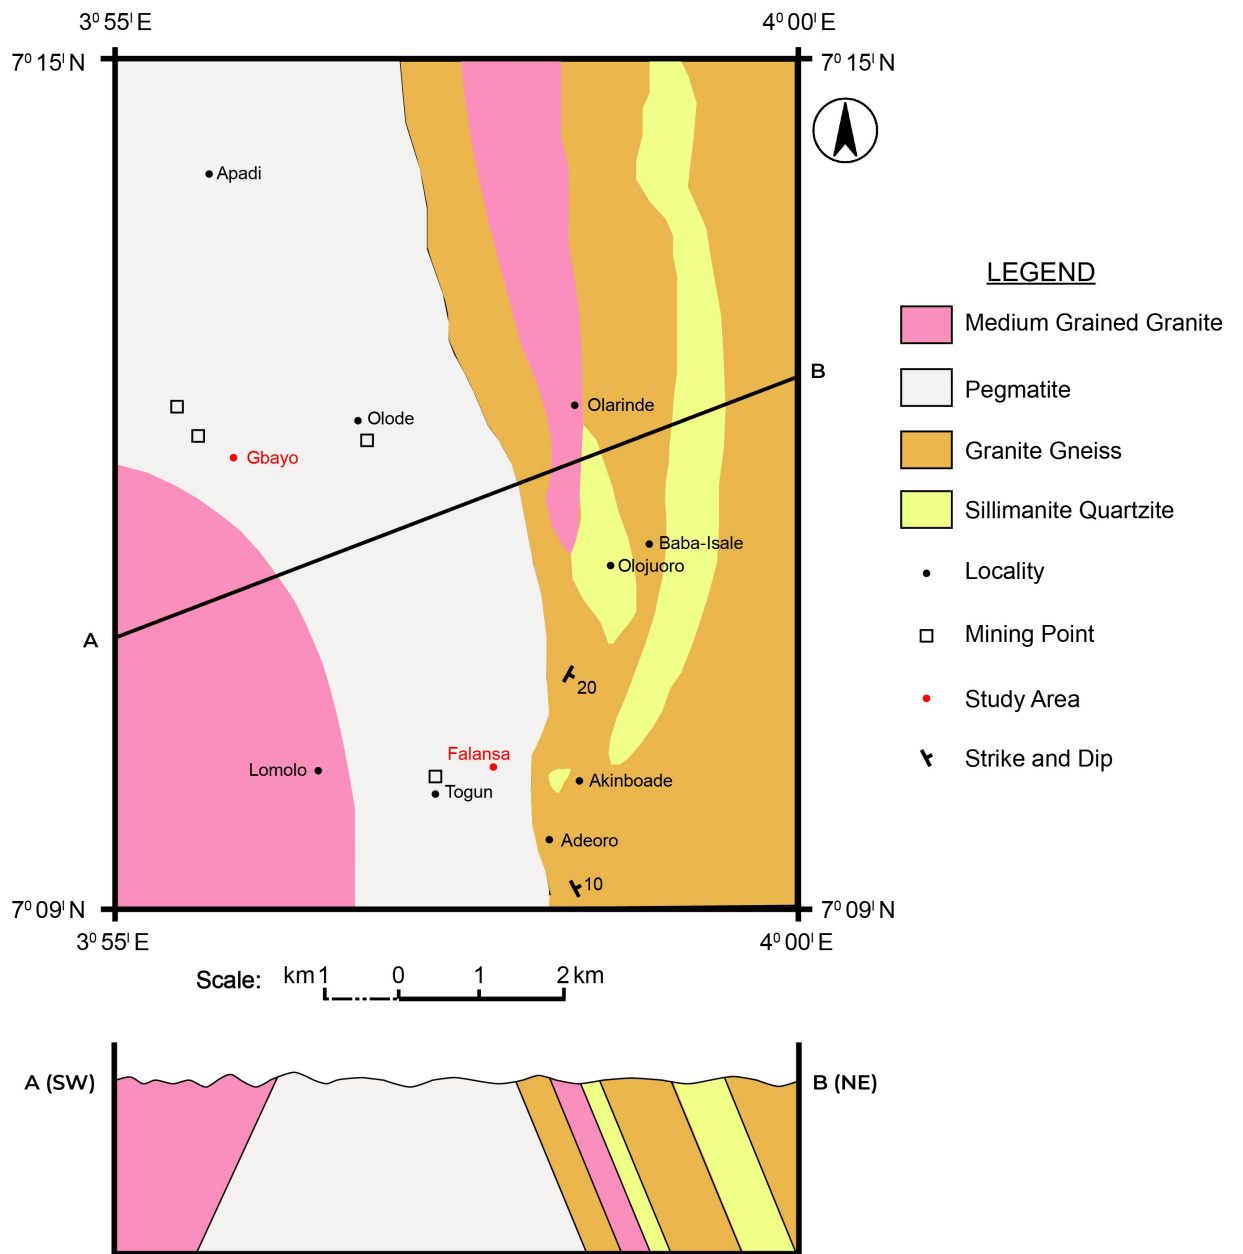

Figure 4.7: Geological map of Olode-Coco-Falansa area

#### **4.1.2: Geology of Komu-Igbojaye-Godondoya area:**

The komu area is underlain by granite gneiss, amphibolite, mica schist and pegmatite with quartz veins associated with the larger rock bodies (figure 4.8- 4.14).

##### **Granite Gneiss**

Granite gneisses are the predominant rock type in the Komu area. Mineralogically, they contain biotite, quartz and ferromagnesian minerals with prominent mafic and felsic bands. The less prominent mafic bands are dominantly composed of biotite while the dominant felsic bands are composed mainly of feldspars. Petrographic studies revealed an assemblage of quartz, biotite, microcline and plagioclase. Petrographically, biotite was observed as elongated brown crystals and distinct cleavage; alkali feldspar shows low birefringence with low relief while microcline shows crosshatching while quartz is subhedral, clear and elongate with no preferred orientation.

##### **Amphibolites**

Amphibolites occur and are widely distributed in the Komu area. They commonly occur as dark greenish lensoid bodies which are composed of amphiboles, plagioclase and minor quantities of quartz. Petrographic studies revealed the amphiboles are mainly hornblende.

##### **Pegmatites**

In the Komu area, pegmatites occur as intrusives in the gneisses and amphibolites. Pegmatites occur as coarse grained rocks composed of quartz, feldspars and tourmaline of varying length which intrude amphibolites and gneisses with a NNW-SSE trend and gradational contact obvious between pegmatites and host lithologies. As regards gemstone mineralisation, it was observed that large crystals of quartz, k-feldspar and micas occur closer to areas with gemstone mineralisation.

Petrographically, plagioclase, quartz, microcline, biotite, tourmaline and muscovite were observed. Quartz is characterised by low relief, and occurs as an interwoven intergrowth with feldspars which vary from plagioclase to microcline while perthite was observed in some sections (figure 4.15-4.17).

Figure: 4.18: Geological map of Komu area.

### 4.1.3: Geology of Idiyan area

The Idiyan area is dominated by mica schist, granite gneisses, and migmatites with NW-SE trending pegmatites intruding the quartz mica schists. Granite gneisses around the Idiyan area have a NNE-SSW trend, they are medium grained, grey, and slightly foliated; biotite, quartz and feldspars observed on hand specimen. Mica schist in the Idiyan area occurs as low lying disjointed, highly weathered outcrops with an N-S strike and they dip westernly (figure 4.19-4.22).

The migmatite gneiss is a mixture of different rock types which include granite gneiss intruded by quartz, pegmatitic and granitic intrusions of various sizes dimensions around Ominigbo and Abidioki. They are characterised by faults, folds and foliation with alternating dark and light layers (figure 4.21). Felsic material occurs as cross cutting veins of coarser granitic material and pegmatite. They are fine to medium grained and color is based on mineral assemblage with pitch and swell structures present in few areas.

In thin section, brown biotite crystals are present with muscovite, quartz and albite. No mymerkitic texture was observed but in some areas on the section, microcline encloses some quartz grains and all minerals display subhedral shape. It is composed of plagioclase, biotite, quartz, and microcline with hornblende occurring with other opaques as accessory minerals. Quartz is abundant and it occurs as subhedral crystals which are medium to fine grained. Alkaline feldspar is mostly microcline and shows typical cross hatch twinning.

The western flank of the study area is overlain by biotite granites which are mafic in color, with greater than 65% mafic minerals and low percentage of felsic minerals. Pegmatites are worked in this area for this feldspar content and gemstone prospects (figure 4.22). Petrographically, composed of quartz and orthoclase with subordinate mica; petrographic analysis revealed a preponderance of microcline (figure 4.23).

Geological maps of the study locations are shown in figures 4.7, 4.18 and 4.24.

## **4.2: Geochemistry and fluid inclusion study of pegmatites**

Major, trace and rare elemental concentration of whole rock pegmatites and extracts are presented in tables 4.1-4.15 while results of fluid inclusion analysis is presented in tables 4.17- 4.30.

### **4.2.1: Geochemistry of pegmatite**

#### **4.2.1.1: Major elemental concentration**

##### **Whole rock pegmatite and feldspar extracts**

Geochemical analytical results (table 4.1- 4.3; tables 4.4 -4.15), revealed pegmatites in the locations have SiO<sub>2</sub> ranging from 47.76% to 82.17%. Samples from Omo-Oba had the lowest SiO<sub>2</sub> concentration while pegmatites from Idiyan had the highest SiO<sub>2</sub> concentration. TiO<sub>2</sub> ranges from 0.01 to 0.34%, samples from Owode had the lowest TiO<sub>2</sub> concentration while pegmatites from Idiyan had the highest TiO<sub>2</sub> concentration; Al<sub>2</sub>O<sub>3</sub> ranges from 9.84% to 18.92% with samples from Idiyan having the lowest Al<sub>2</sub>O<sub>3</sub> concentration while pegmatites from Omo-Oba had the highest Al<sub>2</sub>O<sub>3</sub> concentration. Fe<sub>2</sub>O<sub>3</sub> ranges from 0.20% to 4.25% with samples from Falansa having the lowest Fe<sub>2</sub>O<sub>3</sub> concentration while pegmatites from Omo-Oba had the highest Fe<sub>2</sub>O<sub>3</sub> concentration.

For whole rock pegmatites, other oxides ranged: MnO (0.01% to 1.21%), MgO (0.02% to 1.21%), CaO (0.11% to 2.24%), Na<sub>2</sub>O (0.09% to 10.16%), K<sub>2</sub>O (0.08% to 11.36%) and P<sub>2</sub>O<sub>5</sub> (0.01% to 0.23%). Highest concentrations of MnO, MgO, CaO, Na<sub>2</sub>O, K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub> in whole rock pegmatites were observed at Doya, Omo-oba, Omo-oba, Balogun-Ojo and Owode respectively while lowest concentration of MnO, MgO, CaO, Na<sub>2</sub>O, K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub> were observed at Falansa, Doya, Falansa, Omo-Oba and Balogun-Ojo respectively.

For feldspar extracts, SiO<sub>2</sub> ranges from 43.09% to 73.70%. Feldspar extracts from Omo-Oba had the lowest SiO<sub>2</sub> concentration while feldspar extracts from Doya had the highest SiO<sub>2</sub> concentration. TiO<sub>2</sub> ranges from 0.002 to 0.02%, feldspar extracts from Falansa had the lowest TiO<sub>2</sub> concentration while feldspars extracts from Omo-Oba had the highest TiO<sub>2</sub> concentration; Al<sub>2</sub>O<sub>3</sub> ranges from 16.38% to 21.13% with feldspar extracts from Doya having the lowest Al<sub>2</sub>O<sub>3</sub> concentration while feldspar extracts from Balogun-Ojo had the highest Al<sub>2</sub>O<sub>3</sub> concentration. Fe<sub>2</sub>O<sub>3</sub> ranges from 0.10% to 0.61%, feldspar extracts from Gbayo had the lowest Fe<sub>2</sub>O<sub>3</sub> concentration while feldspars extracts from Doya had the highest Fe<sub>2</sub>O<sub>3</sub> concentration.

Table 4.1: Major elements analytical results for whole rock pegmatites

For feldspar extracts, other oxides range is as follows; MnO (0.01% to 0.95%), MgO (0.01% to 0.09%), CaO (0.04% to 2.61%), Na<sub>2</sub>O (0.23% to 8.81%), K<sub>2</sub>O (0.22% to 12.66%) and P<sub>2</sub>O<sub>5</sub> (0.01% to 0.22%). Highest concentrations of MnO, MgO, CaO, Na<sub>2</sub>O, K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub> in feldspar extracts were observed at Doya, Omo-Oba, Balogun-Ojo, and Omo-Oba respectively while lowest concentration of MnO, MgO, CaO, Na<sub>2</sub>O, K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub> were observed at Idiyan,, Falansa Omo-Oba, Coco and Idiyan respectively.

### **Mica extracts**

#### **Muscovite extracts**

For muscovite extracts, SiO<sub>2</sub> ranges from 45.51% to 52.20. Muscovite extracts from Abuja leather had the lowest SiO<sub>2</sub> concentration while muscovite extracts from Coco had the highest SiO<sub>2</sub> concentration. TiO<sub>2</sub> ranges from 0.04 to 0.13%, muscovite extracts from Gbayo had the lowest TiO<sub>2</sub> concentration while muscovites extracts from Abuja leather had the highest TiO<sub>2</sub> concentration; Al<sub>2</sub>O<sub>3</sub> ranges from 31.18% to 34.81% with muscovite extracts from Coco having the lowest Al<sub>2</sub>O<sub>3</sub> concentration while muscovite extracts from Falansa had the highest Al<sub>2</sub>O<sub>3</sub> concentration. Fe<sub>2</sub>O<sub>3</sub> ranges from 1.92% to 3.32%, muscovite extracts from Balogun-Ojo had the lowest Fe<sub>2</sub>O<sub>3</sub> concentration while muscovites extracts from Abuja leather had the highest Fe<sub>2</sub>O<sub>3</sub> concentration.

Other major oxides in the muscovite extracts are as follows; MnO (0.05% to 0.17%), MgO (0.05% to 0.38%), CaO (0.01% to 0.04%), Na<sub>2</sub>O (0.65% to 1.31%), K<sub>2</sub>O (8.01% to 10.09%) and P<sub>2</sub>O<sub>5</sub> (0.01% to 0.04%). Highest concentrations of MnO, MgO, CaO, Na<sub>2</sub>O, K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub> in muscovite extracts were observed at Owode, Coco, Balogun-ojo, Coco, Coco and Balogun-Ojo respectively while lowest concentration of MnO, MgO, CaO, Na<sub>2</sub>O, K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub> were observed at Coco, Idiyan, Gbayo, Gbayo, Coco and Idiyan respectively.

#### **Biotite extracts**

For biotite extracts, SiO<sub>2</sub> ranges from 35.22% to 45.21%. Biotite extracts from Idiyan had the lowest SiO<sub>2</sub> concentration while biotite extracts from Balogun-Ojo had the highest SiO<sub>2</sub> concentration. TiO<sub>2</sub> ranges from 0.24 to 2.16%, biotite extracts from Abuja leather had the lowest TiO<sub>2</sub> concentration while biotites extracts from Balogun-Ojo had the highest TiO<sub>2</sub> concentration; Al<sub>2</sub>O<sub>3</sub> ranges from 17.80% to 32.78% with

biotite extracts from Balogun-Ojo having the lowest Al<sub>2</sub>O<sub>3</sub> concentration while biotite extracts from Abuja leather had the highest Al<sub>2</sub>O<sub>3</sub> concentration. Fe<sub>2</sub>O<sub>3</sub> ranges from 11.83% to 19.79%. Biotite extracts from Balogun-Ojo had the lowest Fe<sub>2</sub>O<sub>3</sub> concentration while biotites extracts from Idiyan had the highest Fe<sub>2</sub>O<sub>3</sub> concentration.

For biotite extracts, other oxides ranged; MnO (0.08% to 1.69%), MgO (1.57% to 8.55%), CaO (0.09% to 0.86%), Na<sub>2</sub>O (0.68% to 2.40%), K<sub>2</sub>O (0.09% to 7.37%) and P<sub>2</sub>O<sub>5</sub> (0.01% to 0.52%). Highest concentrations of MnO, MgO, CaO, Na<sub>2</sub>O, K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub> in biotite extracts were observed at Idiyan, Idiyan, Omo-oba, Abuja leather, Balogun-Ojo and Omo-Oba respectively while lowest concentration of MnO, MgO, CaO, Na<sub>2</sub>O, K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub> were observed at Omo-oba, Abuja leather, Abuja leather, Balogun-Ojo, Idiyan an Omo-Oba respectively.

#### 4.2.1.2: Trace elemental concentration

Range of selected trace elements (in ppm) in whole rock pegmatites are as follows (table 4.2): U (0.04-13) Th (0.1-13), W (97-933), Sn (1.0-23.0), Be (2-384), Rb (6.0-668.0), Ta (0.5-76.1), Nb (0.6-72.9), Sr (3.0-134.0), Ba (4.0-630.0) and Cs (0.7-49.6). Whole rock pegmatite samples from Doya has elevated concentration of Be relative to other pegmatites which had concentration less than 50ppm except one of the samples from Falansa which also revealed elevated concentration of Be. Samples from Doya also revealed highest concentration of Nb (67ppm) and Ta (76ppm). For W, all whole rock pegmatites have values in excess of 97ppm with one of the samples from Omo-Oba having the highest concentration (figure 4.25-4.30).

Range of selected trace elements (in ppm) in feldspar extracts are as follows: U (0.11-5.08) Th (0.1-2.8), W (118.0-600.0), Sn (1.0-15.0), Be (3-171), Rb (9.0-976.0), Ta (0.3-69.1), Nb (0.6-61.4), Sr (8.0-131.0), Ba (4.0-2260.0) and Cs (0.9-351.0). Be, Nb and Ta concentration is generally low in feldspars with concentration below 10ppm, 20ppm and 8ppm respectively in all samples except the feldspar extract sample from Doya with concentration of 171ppm, 61ppm and 69ppm for Be, Nb and Ta. Furthermore, W concentration varies in feldspar extracts with values above 118ppm in all extracts; with elevated concentrations in excess of 590ppm recorded in feldspar extracts from Omo-Oba and Coco (figure 4.31-4.35).

Range of selected trace elements (in ppm) in muscovite extracts are as follows: U (0.03-2.8) Th (0.1-0.7), W (17-214), Sn (2.0-319.0), Be (15-72), Rb (45->1000.0), Ta (32.8-107.0), Nb (237.0-330.0), Sr (5.0-17.0), Ba (4.0-82.0) and Cs (0.7-49.6).

Compared to other mineral extracts and whole rock pegmatites, muscovite extracts revealed the lowest concentration values of W and the highest concentration values of Sn, Nb and Ta. All muscovite extracts from the study have with the exception of Balogun-Ojo and Owode samples have Sn concentration above 45ppm, Nb values are above 237ppm in all muscovite extracts, values higher than Nb concentration in whole rock and feldspar extracts while 107ppm of Ta; the highest Ta value in pegmatites and extracts in this study was recorded in muscovite extracts from Abuja leather area. Highest concentrations of Nb and Sn were also recorded in samples from Abuja Leather (figure 4.36 - 4.41).

Figure 4.33: Cs concentration in feldspars from the different locations

Figure 4.34: Ta concentration in feldspars from the different locations

Figure 4.35: W concentration in feldspars from the different locations

Range of selected trace elements (in ppm) in biotite extracts are as follows: U (0.56-43.0), Th (0.2-64), W (28.0-699.0), Sn (4.0-70.0), Be (2-5), Rb (3.0-6373.0), Ta (1.2-68.7), Nb (04.8-312.0), Sr (11.0-49.0), Ba (12.0-1650.0) and Cs (0.7-475.0). Compared to muscovite extracts, the biotite extracts have elevated concentration of W in excess of 326 in all locations except Omo-Oba but lower concentrations of Ta which is below 27ppm in all locations except Balogun-Ojo with Ta concentration of 69ppm (figure 4.42-4.46)

#### **4.2.1.3: Rare Earth Elemental concentration**

Pegmatite whole rock samples revealed low to moderate REE abundance; the value ranged 0.4-555.8ppm. Range of selected rare earth elements in whole rock pegmatites are as follows (table 4.3): La (0.14-192.0ppm), Nd (0.1-60.0ppm), Eu (0.1-2.16ppm), Sm (0.2-5.68ppm), Gd (0.04-4.8ppm), Ce (0.08-269.0ppm), Er (0.02-2.67ppm) and Yb (0.01-4.32ppm). REE abundance in feldspar extracts is low (0.2-58.4ppm). Selected rare earth elements in feldspar extracts ranged (table 4.15): La (0.25-20.40ppm), Nd (0.28-6.32ppm), Eu (0.1-0.75ppm), Sm (0.4-1.06ppm), Gd (0.2-1.93ppm), Ce (0.12-28.20ppm), Er (0.02-0.3 ppm) and Yb (0.02-0.31ppm).

REE abundance in muscovite extracts is low (0.2-3.5ppm). Selected rare earth elements in feldspar extracts ranged (table 18): Nd (0.05-0.35ppm), Sm (0.1-0.21ppm), Gd (0.02-0.5ppm), Ce (0.13-28.20ppm), Er (0.02-0.3 ppm) and Yb (0.02-0.31ppm). For biotite extracts, REE abundance is low (0.2-58.4ppm). Selected rare earth elements in biotite extracts ranged (table 18): La (0.25-20.40ppm), Nd (0.28-6.32ppm), Eu (0.1-0.75ppm), Sm (0.4-1.06ppm), Gd (0.2-1.93ppm), Ce (0.12-0.64ppm), Er (0.02-0.3 ppm), Yb (0.04-0.25ppm) and Yb (0.04-0.25ppm).

#### **4.2.1.4: Comparison of selected trace elemental concentrations in whole rock, feldspars, biotite and muscovite extracts**

Comparison of trace elemental concentration of Sn, Zn, W, Ta, Nb and Cs was also carried out to assess the mineralisation pattern of these elements within the different sample types analysed. Trace elemental plots of samples from Balogun-Ojo (figures 4.47-4.48) revealed higher concentration of Cs, Ta and Nb in the biotite and muscovite extracts. Feldspars and whole rocks have lower concentration of Cs, Ta and Nb; W concentration showed no preference for any mineral phase while higher concentration of Zn was observed in biotite and muscovite extracts.

In Abuja-leather samples, elevated concentrations of Cs, Ta, Nb and Sn was observed in muscovite extracts compared to other extracts and whole rock samples, high concentration of Zn was observed in biotite extracts and W shows no preference for any mineral phase (figure 4.49-4.50).

Plots for whole rock pegmatites and extracts from Idiyan area revealed W has no preference for any mineral phase while Sn is elevated in the biotite and muscovite extracts. Elevated concentration of Zn was also observed in biotite extracts while elevated concentration of Cs and Nb was observed in biotites and muscovite extracts; feldspars extracts also revealed high Cs concentration (figure 4.51-4.52). In the Omo-Oba area, results also indicate elevated concentration of Nb, Cs and Zn in biotite extracts (figure 4.53-4.54).

Prefential enrichment of some elements observed in the biotite and muscovite extracts is possibly due to the ability of the micas to incorporate a wide range of rare elements by substitutions at various sites in its crystal structure (Belyankina and Petrov 1983; Bailey, 1984).

#### 4.2.1.5: Discussion

$\text{Na}_2\text{O}-\text{Al}_2\text{O}_3-\text{K}_2\text{O}$  ternary plot and the plot of A/NK against A/CNK revealed pegmatites are peraluminous with the aluminium saturation index (ASI) greater than 1.0 in all samples with the exception of the samples from Omoba and Idiyan which are metaluminous (figure 4.55-4.56).

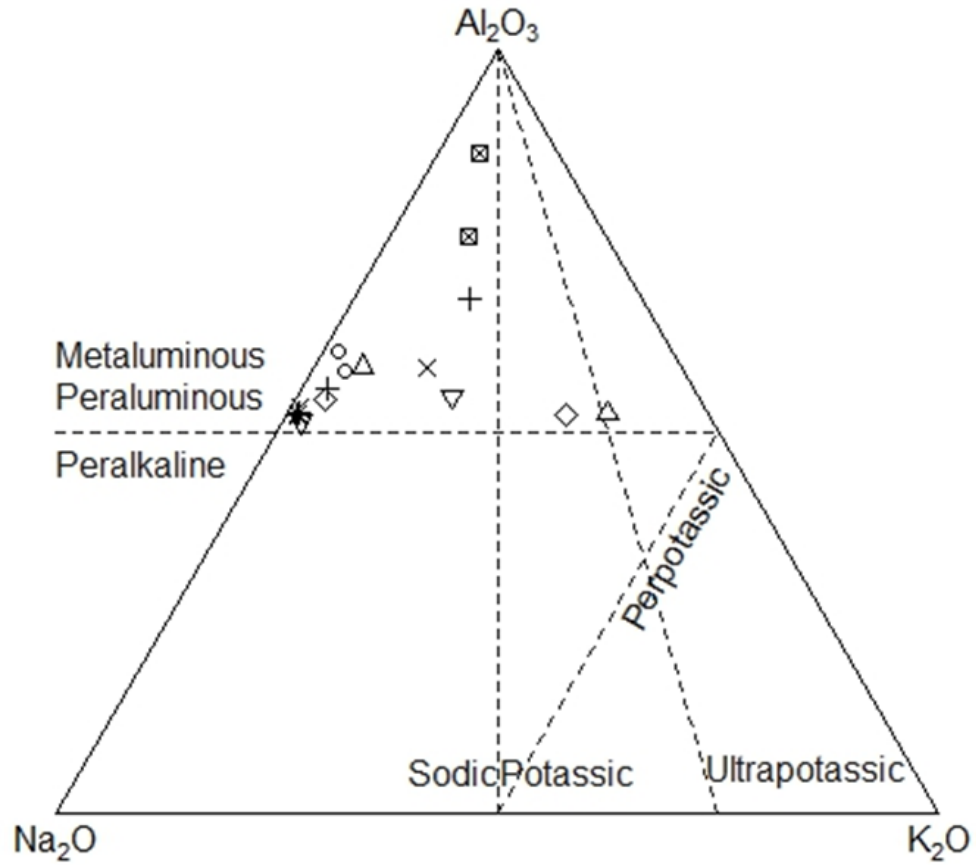

High levels of fractionation of lithophilic elements (e.g. Rb, Cs) is believed to be a common characteristics of rare metal pegmatite (Garba, 2003) During late fractional crystallisation, there is a decrease in the K/Rb ratio hence the lower the K/Rb, the higher the degree of fractionation crystallisation and the more mineralised the pegmatites.

In this study, some pegmatites do not reveal chemical signatures associated with economically mineralised pegmatite which is delineated by K/Rb ratios, which is below 100 (Tischendorff, 1977). K/Rb ratios range from 26-353 in whole rock pegmatites with about eight of the samples studied having K/Rb ratios less than 100 and only one sample (Doya) revealing high fractionation with K/Rb values of 26 (table 4.16a-e). K/Rb vs Rb plots revealed pegmatites are un-mineralised pegmatites with the exception of the ‘Doya’ sample while the K/Rb vs Ba revealed that pegmatites mostly belong to the muscovite class. From the K/Rb vs Ba plot, pegmatites from Doya are rare element pegmatites while those of Idiyan, Balogun –Ojo, Falansa, Omoba and Owode are muscovite class pegmatites.

The plot of Ta vs Ga shows that the pegmatites from the localities have low mineralisation potential with few of the pegmatite whole rock (Abuja leather, Coco, Doya and Falansa) and biotite samples (Abuja leather, Baba-ode and Doya) plotting above the Beus, (1966) mineralisation line; only one feldspar sample (Doya) reveals mineralisation potential while all muscovite mineral extracts plotted above the Ta-line of mineralisation of Beus, (1966) with some plotting above the Gordiyenko, (1971) mineralisation line. Preferential enrichment in muscovite and biotite extracts is believed to be due to the ability of the muscovite extracts to selectively accommodate certain elements in its crystal lattice during fractional crystallisation.

Similar observation was observed in the plot of Ta vs K/Cs and the Ta vs Cs + Rb plot; this further emphasises the low Ta-Nb mineralisation potential of the pegmatites studied (figure 4.57-4.59).

Sample 1-16 are whole rock pegmatites. 17-27 are feldspar extracts, 28-40 are muscovite extracts and samples 41-48 are biotite extrcats

Fractionation degree of the pegmatites was also assessed using plots of Sr/Rb vs Rb/Ba and Rb/K vs. Sr/Rb (figure 4.60-4.61). The plots show the same trend for pegmatites in the locations with increasing fractionation. Furthermore, Nb/Ta ratio ranges from 0.41-7.74 in whole rock pegmatites, 0.85-6.02 in feldspar extracts, 2.35-7.29 in muscovite extracts and 3.54-12.73 in biotite extracts while Ta/W ranged 0.01-0.80 in whole rock pegmatites, 0.01-0.25 in feldspar extracts, 0.31-4.95 in muscovite extracts and 0.01-0.92 (table 4.4) in biotite extracts which suggest the pegmatites whole rock and the extracts have higher concentration of Nb and W with respect to tantalum and could be more a Niobium and Tungsten prospect (figure 4.62-4.66).

Rare earth elemental normalisation pattern revealed two distribution patterns with no preferential enrichment of LREE or HREE. Normalisation plots revealed no Ce anomalies but they revealed negative Europium anomaly is indicative of fractionation and late metasomatic effects (Taylor et al., 1986). Based on Eu/Eu\* values and the presence/absence of Eu anomalies. Negative Eu anomalies was observed in all samples with K/Rb less than 100 and in just one sample with K/Rb value above 100. In this group of samples, Eu/Eu\* values ranged 0.04-0.65, with an average of 0.17 while in the samples with higher K/Rb values, Eu/Eu\* values ranges from 0.90-3.03 with an average of 1.48 which implies variable fractionation in the pegmatite studied.

In the other set of pegmatites with low K/Rb values, incompatible elemental plots revealed as expected, an enrichment in Cs, Rb, Ta, Nb relative to primordial mantle (values after Sun and McDonough, 1985) and a depletion in Ba, K and Sr. Enrichment in Rb, Cs, Ta and Nb with the depletion in K and Ba suggesting the pegmatites are formed as a result of progressive fractionation; and Rb enrichment coupled with Ba depletion is a due to late stage fractional crystallisation (figure 4.67-4.70).

In the other set of pegmatites, with high K/Rb values, negative Ce and negative Europium anomalies were not observed though some samples have a low positive Eu anomaly. It is inferred from the negative Eu and Ce anomalies that these pegmatites did not undergo considerable fractionation and they were not subjected to considerable metasomatism. For these samples, incompatible element plots revealed various patterns. It revealed a lower enrichment in Cs, Rb, Nb and in some cases Ta as well as lower depletions in Sr and Ba which suggests they were formed from a more unfractionated melt.

Furthermore, in pegmatites with low K/Rb ratios, (La/Yb)<sub>N</sub> ratios ranged 0.26-3.47 and they range 1.37-18.54 in pegmatites with higher K/Rb values which further indicates the difference in fractionation pattern between the two groups of pegmatites.

### 4.3 Fluid inclusion studies

#### 4.3.1 Description of Fluid Inclusion Types

Availability, type and distribution of inclusions were determined by petrographic study on the doubly polished wafer. Inclusions observed were classified using the petrographic criteria of Shepherd et al., (1985) through a combination of distribution (e.g. isolated individuals or as trails along annealed fractures), phases present at room temperature and composition.

Using these criteria, the fluid inclusions present in a grain can were classified as primary (isolated individuals which are commonly aligned to crystal growth planes), secondary (fluid inclusion trails crosscut grains and are aligned with and contained within annealed fractures) and pseudosecondary (fluid inclusion trails begin and terminate abruptly within individual crystals). For this study, only primary and pseudosecondary inclusions were analysed as these fluid inclusions provide data on pressure, temperature and composition (PTX) properties of fluid trapped during quartz crystallisation and subsequent fluid migration events.

Inclusions occur as isolated individuals or in trails along annealed microfractures that cross-cut quartz grains in all samples. Fluid inclusion morphologies range from ellipsoidal to tabular to irregular and the sizes range from  $<2 \mu\text{m}$  to  $100 \mu\text{m}$  (figure 4.71). Three types of aqueous inclusions (type 1, type 2 and type 3) were observed (table 4.17-4.18).

**Type 1** inclusions are two-phase liquid + vapour (L+V; L>V) with high degree of fill (F) i.e.  $F \sim 0.90$  ( $F = \frac{\text{vol. of liquid}}{\text{vol. of liquid} + \text{vapour}}$ ). They occur in all samples hosted in quartz grains as isolated individuals, in random groupings and as trails along post-crystallisation annealed fractures with size ranging from  $2 \mu\text{m}$  to  $100 \mu\text{m}$ . They display a range of shapes varying from tabular to ellipsoidal to irregular.

**Type 2** are three phase (liquid + vapour + solid) inclusions with a high degree of fill i.e.  $F \sim 0.85$ . They are ellipsoidal in shape with size of  $2 \mu\text{m}$  to  $15 \mu\text{m}$ . The trapped solid phases are generally  $< 3 \mu\text{m}$  in the longest dimension. They occur in trails or as isolated individuals within quartz grains. They are uncommon and only occur in five samples.

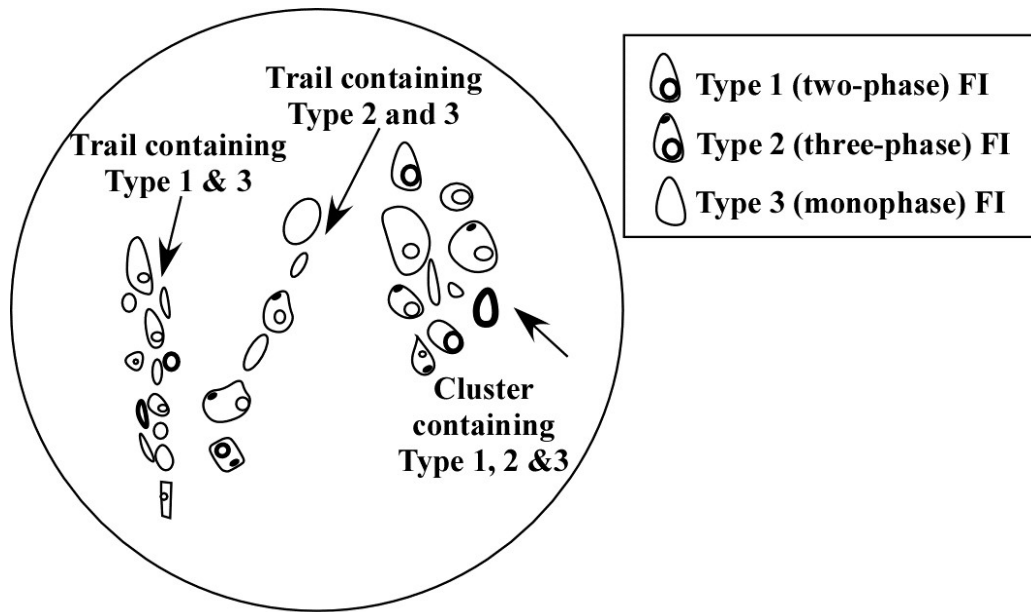

Figure 4.71: Schematic representation of the occurrence of quartz-hosted FIs in all samples.

Table 4.17: Classification of fluid inclusions observed in the study

| <b>TYPES</b>          | <b>1</b>                                    | <b>2</b>                                 | <b>3</b>                                    |
|-----------------------|---|--|---|
| <b>Phases Present</b> | L + V                                       | L + V + S                                | L   |
| <b>Composition</b>    | Aqueous                                     | Aqueous                                  | Aqueous                                     |

Figure 4.84: Photomicrographs of sample GB 001 (Gbayo). (a) General view of typical quartz grain under low magnification. (b) Type 1 and Type 3 forming trails along annealed fracture.

Figure 4.85: Photomicrographs of sample GB 001 (Gbayo) (c) Type 1 showing irregular shape due to stretching. (d) Multiple Type 1 inclusions displaying a variety of morphologies.

Figure 4.86: Photomicrographs of sample GB 002 (Gbayo). (a) General view of typical quartz grain under low magnification. (b) Type 1 and Type 3 forming trails along annealed fractures

Figure 4.87: Photomicrographs of sample GB 002 (Gbayo) (c) Multiple Type 1 forming trail along annealed fracture. (d) Higher magnification view of inset from (c) showing irregular shapes of FI and varying vapour bubble volumes.

Figure 4.88: Photomicrographs of sample CO 003 (Coco). (a) General view of typical quartz grain under low magnification. (b) Type 3 forming a trail along an annealed fracture.

Figure 4.89: Photomicrographs of sample CO 003 (Coco) (c) Isolated Type 1. (d) Multiple Type 1 individuals forming cluster.

Figure 4.90: Photomicrographs of sample CO 005 (Coco). (a) General view of typical quartz grain under low magnification. (b) Multiple crosscutting trails containing Type 2 and Type 3 FI

Figure 4.91: Photomicrographs of sample CO 005 (Coco) (c) Trail containing Type 1. (d) Isolated Type 2 (L=Liquid, V=Vapour, S=Solid).

#### **4.3.3.1: Abuja Leather, Komu**

Fluid inclusion microthermometry was carried out on thirteen Type 1 inclusions in sample AB 006 and fifteen Type 1 inclusions in sample AB 007 obtained from Abuja Leather in Komu. The length of inclusions vary from 3.7-9.2 $\mu\text{m}$ ; type 1 inclusions in sample AB 006 homogenise to the liquid phase between 118 $^{\circ}\text{C}$  to 130 $^{\circ}\text{C}$  with mean  $T_{\text{H}}$  value of 125.3 $^{\circ}\text{C}$  (Figure 4.92-4.93, table 4.19-4.20).  $T_{\text{LM}}$  values ranges from -1.4 $^{\circ}\text{C}$  to -4.8 $^{\circ}\text{C}$  corresponding to salinity values of 2.4 to 7.6 eq. wt.% NaCl. Type 1 inclusions in sample AB 007 homogenise to the liquid phase between 80 $^{\circ}\text{C}$  and 99 $^{\circ}\text{C}$  with a mean  $T_{\text{H}}$  value of 89.2 $^{\circ}\text{C}$ . TLM values ranges from -3.9 $^{\circ}\text{C}$  to -8.2 $^{\circ}\text{C}$  corresponding to salinity values of 6.3 to 11.9 eq. wt.% NaCl (mean = 9.1 eq. wt.% NaCl).

#### **4.3.3.2: Omoba in Okeho**

Fluid inclusion microthermometry was carried out on seven Type 1, six Type 2 inclusions in sample OM 009 and eleven Type 1 inclusions in sample OM 010. The length of inclusions vary from 5.1-20.6 $\mu\text{m}$ ; type 1 inclusions in sample OM 009 homogenise to the liquid phase at 159 $^{\circ}\text{C}$  and 259 $^{\circ}\text{C}$  with a mean  $T_{\text{H}}$  value of 204 $^{\circ}\text{C}$  (Figure 4.94-4.95, table 4.21-4.22). TLM values ranges from -3.2 $^{\circ}\text{C}$  to -5.6 $^{\circ}\text{C}$  corresponding to salinity of 5.3 to 8.7 eq. wt.% NaCl (mean = 6.7 eq. wt.% NaCl).

Type 2 inclusions in sample OM 009 homogenise to the liquid phase (solid phase does not homogenise) between 318 $^{\circ}\text{C}$  and 385 $^{\circ}\text{C}$  with mean  $T_{\text{H}}$  value of 327.4 $^{\circ}\text{C}$ . Type 1 inclusions in sample OM 010 homogenise to the liquid phase at 138 $^{\circ}\text{C}$  to 214 $^{\circ}\text{C}$  with a mean  $T_{\text{H}}$  value of 185.2 $^{\circ}\text{C}$ .  $T_{\text{LM}}$  values ranges from -0.4 $^{\circ}\text{C}$  to -1.7 $^{\circ}\text{C}$  which corresponds to salinity values of 0.7 and 3.1 eq. wt.% NaCl (mean = 1.8 eq. wt.% NaCl).

Table 4.19: Microthermometric result of Abuja Leather samples

Sample AB 006

| Number | Sample | Type and Composition | Degree of Fill (F) | Length ( $\mu\text{m}$ ) | $T_{LM}$ ( $^{\circ}\text{C}$ ) | Salinity (eq.wt.% NaCl) | $T_H$ ( $^{\circ}\text{C}$ ) | To     | Setting | Host Mineral |
|--------|--------|----------------------|--------------------|--------------------------|---------------------------------|-------------------------|------------------------------|--------|---------|--------------|
| 1      | Chip 2 | Type 1 Aqueous       | 0.90               | 4.8                      | 4.8                             | 7.6                     | 125.8                        | Liquid | Trail   | Quartz       |
| 2      | Chip 2 |                      | 0.90               | 5.3                      | 4.2                             | 6.7                     | 126.3                        | Liquid | Trail   |              |
| 3      | Chip 2 |                      | 0.90               | 8.2                      | 2.5                             | 4.2                     | 130.3                        | Liquid | Trail   |              |
| 4      | Chip 2 |                      | 0.90               | 4.6                      | 4.5                             | 7.2                     | 118.2                        | Liquid | Trail   |              |

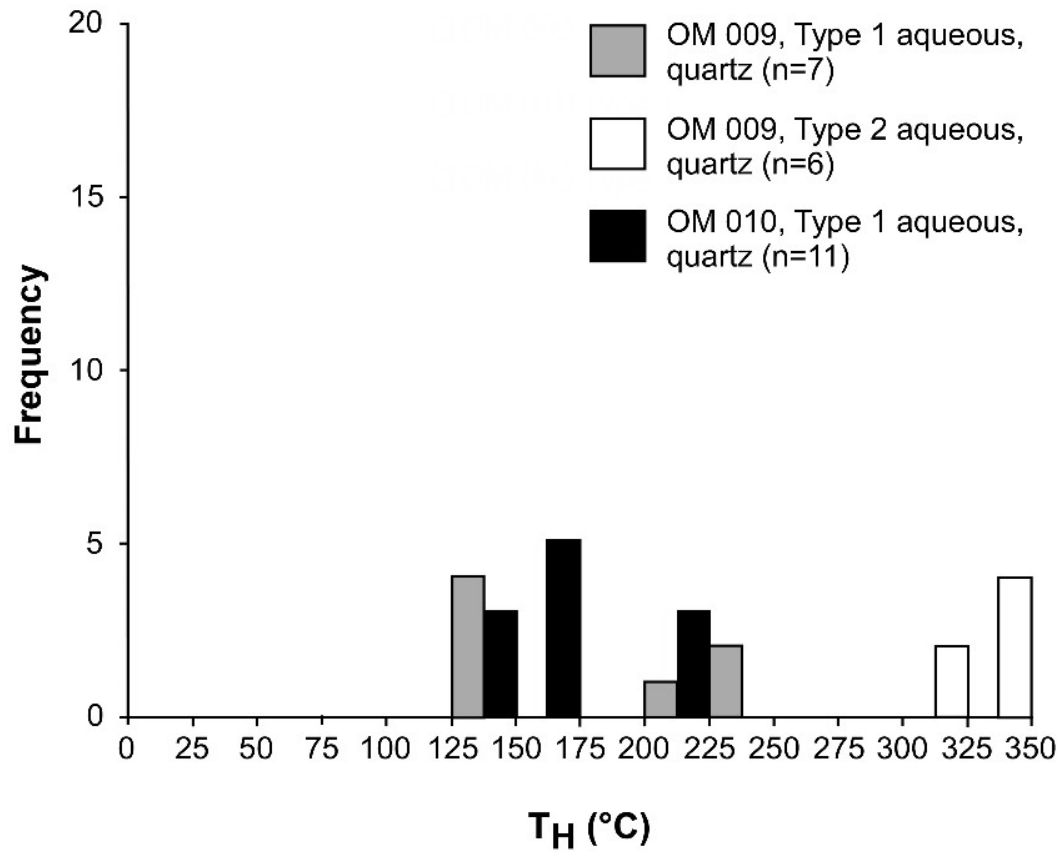

Figure 4.94:  $T_H$  frequency distribution histogram for Type 1 (n=18) and Type 2 (n=6) FIs in Omoba samples.

Figure 4.95: T<sub>H</sub> versus salinity plot for Omoba samples.

#### 4.3.3.3: Owode, Ibarapa

Microthermometry was carried out on eleven Type 1 inclusions and two Type 2 inclusions in sample OW 003. It was also carried out on eleven Type 1 inclusions and one Type 2 inclusion in sample OW 005. The length of inclusions vary from 2.9-20.1 $\mu\text{m}$ ; type 1 inclusions in sample OW 003 homogenise into the liquid phase between 109 $^{\circ}\text{C}$  and 229 $^{\circ}\text{C}$  with mean  $T_{\text{H}}$  value of 167 $^{\circ}\text{C}$  (Figure 4.96-4.97, table 4.23-4.24).  $T_{\text{LM}}$  occurs between -0.2 $^{\circ}\text{C}$  and -8.6 $^{\circ}\text{C}$  corresponding to salinity values of 0.4 and 12.4 eq. wt.% NaCl (mean = 6.9 eq. wt.% NaCl). Type 2 inclusions in sample OW 003 homogenise to the liquid phase (solid phase does not homogenise) at 142.5 $^{\circ}\text{C}$  to 146.3 $^{\circ}\text{C}$  with a mean  $T_{\text{H}}$  value of 144.4 $^{\circ}\text{C}$ . Type 1 inclusions in sample OW 005 homogenise to the liquid phase between 152 $^{\circ}\text{C}$  and 172 $^{\circ}\text{C}$  with mean  $T_{\text{H}}$  value of 161.2 $^{\circ}\text{C}$ .  $T_{\text{LM}}$  occurs between -0.1 $^{\circ}\text{C}$  and -1.5 $^{\circ}\text{C}$  corresponding to salinity values of 0.2 to 2.6 eq. wt.% NaCl (mean = 1.2 eq. wt.% NaCl). The Type 2 inclusion in sample OW 005 homogenises to the liquid phase (solid phase does not homogenise) at 162.5 $^{\circ}\text{C}$ .

#### 4.3.3.4: Gbayo, Olode

Fluid inclusion microthermometry was carried out on twenty-one Type 1 aqueous-rich inclusions in sample GB 001 and twelve Type 1 aqueous-rich inclusions and four Type 2 inclusions in sample GB 002. Type 1 inclusions in sample GB 001 homogenise to the liquid phase between 145°C and 156°C with a mean  $T_H$  value of 151°C (Figure 4.98-4.99, table 4.25-2.26).  $T_{LM}$  occurs between -17.2°C and -19.4°C corresponding to salinity values of 20.4 to 22 eq. wt.% NaCl (mean = 21.3 eq. wt.% NaCl). Type 1 inclusions in sample GB 002 homogenise to the liquid phase between 162°C and 175°C with a mean  $T_H$  of 169°C.  $T_{LM}$  occurs between -4.1°C and -6.2°C corresponding to salinity values of 6.6 to 9.5 eq. wt.% NaCl (mean = 7.8 eq. wt.% NaCl). Type 2 inclusions in sample GB 002 homogenise to the liquid phase between 146°C and 158°C. The solid phase homogenises to the liquid phase at 175°C.

Figure 4.99: T<sub>H</sub> versus salinity plot for Gbayo, Olode samples.

#### 4.3.3.5: Coco, Olode

Fluid inclusion microthermometry was carried out on fourteen one Type 1 aqueous-rich inclusions in sample CO 003 and ten Type 1 inclusions and five Type 2 inclusions from sample CO 005. Type 1 inclusions in sample CO 003 homogenise to the liquid phase between 122°C and 142°C with a mean  $T_H$  value of 132°C (Figure 4.100-4.101, table 4.27-4.28).  $T_{LM}$  values ranges from -0.6°C to -2.1°C corresponding to salinity values of 1.1 to 3.5 eq. wt.% NaCl (mean = 2.2 eq. wt.% NaCl). Type 1 inclusions in sample CO 005 define two fluid populations (Population A and Population B).

**Population A** (n=3) which homogenise to the liquid phase between 150°C and 156°C with a mean  $T_H$  value of 153°C.  $T_{LM}$  occurs between -1.5°C and -3.4°C which corresponds to salinity values of 2.6 to 5.6 eq. wt.% NaCl (mean = 4.1 eq. wt.% NaCl). **Population B** (n = 7) homogenise to the liquid phase between 238°C and 261°C with a mean  $T_H$  value of 248°C.  $T_{LM}$  occurs between -2.8°C and -3.4°C corresponding to salinity values of 4.6 to 5.6 eq. wt.% NaCl (mean = 5.2 eq. wt.% NaCl). Type 2 inclusions in sample CO 005 homogenise to the liquid phase (solid phase does not homogenise) between 305°C and 312°C.

A summary of the homogenisation properties of the inclusions is also in table 4.29-4.30

Table 4.27: Microthermometric results of Coco samples.

**Sample CO 003**

| Number | Sample | Type and Composition | Degree of Fill (F) | Length ( $\mu\text{m}$ ) | $T_{\text{LM}} (^{\circ}\text{C})$ | Salinity (eq.wt.% NaCl) | $T_{\text{H}} (^{\circ}\text{C})$ | To     | Setting | Host Mineral |

#### **4.3.4: Discussion: Modelling Trapping Pressure and Temperature (P-T) of Aqueous Fluids**

Isochores were constructed to constrain trapping temperature and pressure of fluids using the PVT (Pressure, Volume, Temperature) modelling software FLUIDS. Temperature of homogenisation ( $T_H$ ), calculated salinity (eq. wt% NaCl), for Type 1 aqueous inclusions, were used to generate an isochore for each sample. To model fluid trapping temperatures, a maximum trapping pressure was estimated based upon crystallisation depth for granitoid magmas (1.5 kilobar  $\approx$  5.1km; Hunt et al., 2005).

##### **4.3.4.1: Abuja Leather, Komu**

The microthermometric data used are as follows: sample AB 006,  $T_H = 89.2^\circ\text{C}$ ,  $F = 0.9$ ,  $T_{LM} = -6.0^\circ\text{C}$  and for sample AB 007,  $T_H = 125.3^\circ\text{C}$ ,  $F = 0.9$ ,  $T_{LM} = -2.6^\circ\text{C}$ .

Both temperatures are considered to be low and therefore unrelated to higher temperature magmatic fluids. Assuming a maximum lithostatic pressure of  $\sim 1.5\text{kbar}$  ( $\sim 5\text{ km}$ ) this equates to corrected minimum trapping temperatures of  $\sim 190^\circ\text{C}$ . These modelled temperatures show a temperature correction of about  $65^\circ\text{C}$  for the fluids modelled in this pegmatite (Figure 4.102). The differing  $T_H$  and salinity values between the fluids in AB 006 and AB 007 may represent a dilution trend that indicates an interaction of two fluids, one of which may be of meteoric origin.

##### **4.3.4.2: Omoba, Okeho**

The microthermometric data used for Omoba samples was  $T_H = 165.5^\circ\text{C}$ ,  $F = 0.9$  and  $T_{LM} = -2.1^\circ\text{C}$ . This temperature is considered to be moderate to high and is therefore likely to be related to higher temperature magmatic fluids. Assuming a minimum lithostatic pressure of  $\sim 1.5\text{kbar}$  ( $\sim 5\text{km}$ ) this equates to corrected maximum trapping temperatures of  $\sim 250^\circ\text{C}$ . This modelled temperature shows a temperature correction of about  $85^\circ\text{C}$  for the fluids modelled in this pegmatite (Figure 4.103).

##### **4.3.4.3: Owode, Ibarapa**

The microthermometric data used for Owode samples was  $T_H = 164.9^\circ\text{C}$ ,  $F = 0.85$  and  $T_{LM} = -0.7^\circ\text{C}$ . This temperature is considered to be moderate to high and is therefore likely to be related to higher temperature magmatic fluids. Assuming a maximum lithostatic pressure of  $\sim 1.5\text{ kbar}$  ( $\sim 5\text{km}$ ) this equates to corrected minimum

trapping temperatures of  $\sim 250^{\circ}\text{C}$ . This modelled temperature shows a temperature correction of about  $85^{\circ}\text{C}$  for the fluids modelled in this pegmatite (Figure 4.104).

Figure 4.102: Isochores calculated for Type 1 aqueous FIs in Abuja leather sample. Arrow indicates possible dilution trend.

Figure 4.103: Isochore calculated for Type 1 aqueous FIs in samples from Omoba area.

Figure 4.104: Isochore calculated for Type 1 aqueous FIs in Owode samples.

#### 4.3.4.4: Gbayo, Olode

The microthermometric data used are as follows:

sample GB 001,  $T_H = 150.6^\circ\text{C}$ ,  $F = 0.9$ ,  $T_{LM} = -18.4^\circ\text{C}$ ;

sample GB 002,  $T_H = 168.6^\circ\text{C}$ ,  $F = 0.9$ ,  $T_{LM} = -5^\circ\text{C}$ .

These temperatures are considered to be moderate to high and are therefore likely to be related to higher temperature magmatic fluids. Assuming a maximum lithostatic pressure of  $\sim 1.5\text{kbar}$  ( $\sim 5\text{km}$ ) this equates to a corrected minimum trapping temperature of  $\sim 250^\circ\text{C}$ . These modelled temperatures show a temperature correction of about  $80^\circ\text{C}$  for the fluids modelled in this pegmatite (Figure 4.105). The differing  $T_H$  and salinity values between the fluids in AB 006 and AB 007 may represent a dilution trend that indicates an interaction of two fluids, one of which may be of meteoric origin.

#### 4.3.4.5: Olode

The microthermometric data used are as follows:

Sample CO 003,  $T_H = 131^\circ\text{C}$ ,  $F = 0.85$ ,  $T_{LM} = -1.3^\circ\text{C}$ ;

Sample CO 005,  $T_H = 248.4^\circ\text{C}$ ,  $F = 0.9$ ,  $T_{LM} = -2.5^\circ\text{C}$ .

Temperatures for CO 003 are considered to be low to moderate and therefore unrelated to higher temperature magmatic fluids. Temperatures for sample CO 005 are considered to be high and therefore the fluids are associated with magmatic activity. Assuming a maximum lithostatic pressure of  $1.5\text{kbar}$  ( $\sim 5\text{km}$ ) this equates to a corrected minimum trapping temperature of  $\sim 325^\circ\text{C}$ . These modelled temperatures show a temperature correction of about  $75^\circ\text{C}$  for the fluids modelled in this pegmatite (Figure 4.106). The differing  $T_H$  and salinity values between the fluids in AB 006 and AB 007 may represent a dilution trend that indicates an interaction of two fluids, one of which may be of meteoric origin.

Figure 4.105: Isochores calculated for Type 1 aqueous FIs in samples from Gbayo. Arrow indicates possible dilution trend.

Figure 4.106: Isochores calculated for Type 1 aqueous FIs in Coco samples. Arrow indicates possible dilution trend.

Based on the data presented above, a qualitative model is generated that shows a pressure-temperature-time (PTt) path of fluid trapping for the pegmatites (Figure 4.107). The fluids trapped initially at Time 1 (Type 2 FI) have relatively high minimum trapping temperatures (i.e. homogenisation  $T \sim 350^{\circ}\text{C}$ ). These may then be the earliest fluids trapped and may be associated with late magmatic-hydrothermal fluids. The trapping of Type 2 fluids is then followed by the trapping of Type 1 fluids (Time 2 and Time 3). Higher ( $\sim 250^{\circ}\text{C}$ ) and lower ( $\sim 160^{\circ}\text{C}$ )  $T_{\text{H}}$  values for Type 1 FI may indicate a dilution trend suggesting interaction between at least two fluids suggesting interaction between very late magmatic and meteoric fluids. Finally, the presence of Type 3 FI indicate a much lower temperature and pressure regime at Time 4 ( $< 50^{\circ}\text{C}$ ).

Figure 4.107: A qualitative pressure-temperature-time (PTt) model for fluid trapping.

## CHAPTER FIVE

### SUMMARY, CONCLUSION AND RECOMMENDATIONS

#### 5.1: Summary

Geochemistry, mineralisation potential and fluid characteristics of pegmatites in selected areas of southwestern Nigeria has been studied. The areas were systematically mapped and mapping revealed pegmatites are associated with different lithological units in the selected areas; these lithologies include: granite gneisses, sillimanite quartzite, pelitic schists, amphibolites and quartz mica schists.

Pegmatites occur as intrusions associated with the different lithologies and are composed of quartz + microcline + muscovite ± biotite. Geochemical analysis reveals silica concentration for whole rock pegmatites while other mineral extracts had lower silica content while alumina concentration varies across the extracts. Across all samples, SiO<sub>2</sub> ranged 35.22-82.17%, CaO ranged 0.01-2.61%, Na<sub>2</sub>O ranged 0.09-10.16%, and P<sub>2</sub>O<sub>5</sub> ranged 0.01-0.23%. Al<sub>2</sub>O<sub>3</sub> ranged 9.84-34.81%, Fe<sub>2</sub>O<sub>3</sub> ranged 0.10-19.70%, MnO ranged 0.01-1.69%, MgO ranged 0.02-8.55% and K<sub>2</sub>O 0.08-12.66% with highest concentration of Al<sub>2</sub>O<sub>3</sub>, TiO<sub>2</sub>, MnO, MgO and Fe<sub>2</sub>O<sub>3</sub> in biotite extracts.

Geochemical analysis revealed low concentration of rare metals. Ta, Nb, Ta, Cs and W had values (in ppm) ranging 0.54-76.00, 0.60-73.00, 0.70-50.00 and 97.00-933.00 in whole rock pegmatites; 0.32-69.00, 0.60-61.00, 0.90-351.00 and 118.00-600.00 in feldspar extracts; 33.00-107.00, 237.00-330.00, 40.00-252.00 and 17.00-214.00 in muscovite extracts; 1.00-69.00, 4.80-312.00, 0.70-475.00 and 28.00-699.00 in biotite extracts while  $\Sigma$ REE (in ppm) in whole rock pegmatites and extracts vary from low to moderate with values ranging 0.39-555.77, 0.19-58.36, 0.16-3.4 and 12.79-486.83 in whole rock, feldspar extracts, muscovite extracts and biotite extracts respectively.

Plots of K/Rb versus Cs, Ta versus Ga, Ta vs Cs, Ta vs Cs + Rb, Ta vs K/Cs as well as the Th/u vs K/Cs revealed low level of Ta-Nb mineralisation the pegmatites and extracts. Nb/Ta and Ta/W ranged from 0.41-7.74 and 0.01-0.80 in whole rock

pegmatites, 0.85-6.02 and 0.01-0.25 in feldspar extracts, 2.35-7.29 in muscovite extracts and 3.54-12.73 and 0.01-0.92 in biotite extracts.

Fluid characterisation using microthermometry on pegmatitic quartz revealed three types of aqueous inclusions. Type 1 are two-phase LV (L>V) inclusions (~2 - 100  $\mu\text{m}$ ) occurring as isolated individuals, in clusters and in trails in quartz. They are primary to pseudosecondary in origin. Microthermometric analyses yield final temperature of melting of ice which ranged  $-19.5\text{ }^{\circ}\text{C}$  to  $-0.1\text{ }^{\circ}\text{C}$  which is equivalent to salinity of 0.18 to 22 eq. wt. % NaCl while  $T_{\text{H}}$  values ranged from  $80\text{ }^{\circ}\text{C}$  to  $261\text{ }^{\circ}\text{C}$ .

Type 2 inclusions are three-phase (L+V+S) inclusions (~2-15 $\mu\text{m}$ ) occurring in isolation and in trails. They are primary to pseudosecondary in origin. Microthermometric analyses yield  $T_{\text{H}}$  values of  $143\text{ }^{\circ}\text{C}$  to  $\sim 335\text{ }^{\circ}\text{C}$  with higher  $T_{\text{H}}$  values inferred to be magmatic in origin. Two distinct solid phases were being observed in samples obtained from Omoba, Owode and Coco, both types are  $<3\mu\text{m}$  in longest dimension and may indicate the presence of sylvite (KCl).

Type 3 are monophasic (liquid) aqueous inclusions at room temperature and occur as isolated individuals, as clusters and in trails that also contain Type 1 and Type 2 in quartz. Type 3 is primary to pseudosecondary in origin and is indicative of trapping temperatures of below  $50\text{ }^{\circ}\text{C}$ ; and they record migration of low temperature aqueous fluids.

## **5.2: Conclusion**

Based on geochemical analytical results and geochemical variation plots, pegmatites in the studied locations have low level of Ta mineralisation and moderate levels of Nb and W mineralisation in muscovite extracts compared to other extracts. Fluid characterisation revealed pegmatites are magmatic in origin but meteoric fluids were involved in pegmatite genesis in some of the areas.

## **5.3: Recommendations**

1. Fluid inclusion analyses on additional samples should be carried out to consolidate results for each pegmatite.
2. Identification of the solid phases in Type II fluid inclusions should be done using Laser and Raman Microspectroscopy.
